THE ELECTRICAL ENGINEER.

THE

ELECTRICAL ENGINEER.

Conducted by F. L. POPE AND G. M. PHELPS, JR.

PUBLISHED MONTHLY BY

THE ELECTRICAL PUBLISHING CO.,

115 Nassau Street, New York city.

European Agent, F. H. WEBB, 4, The Sanctuary, Westminster, London, S.W., Eng.

TERMS OF SUBSCRIPTION.

United States and Canada,	per annum,	$3.00
Four or more Copies, in Clubs (each)	"	2.50
One Copy, Four Months,		1.00
Great Britain and other Foreign Countries within the Postal Union	"	4.00
Single Copies,		.30

[*Entered at the Post Office at New York, N. Y., as second class mail matter.*]

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

NEW YORK, JANUARY, 1888.

We are pleased to renew our announcement of last year that by arrangement with the ELECTRICAL WORLD, *we are able to offer that excellent weekly journal in conjunction with* THE ELECTRICAL ENGINEER, *for one year to new subscribers for* $5.00. *To those of our present subscribers who desire it we will supply the* ELECTRICAL WORLD *one year for* $2.50

THE WRONG WAY AND THE RIGHT WAY.

A WELL-KNOWN electrician of our acquaintance had occasion a short time since to consult a manufacturer of locomotives, whose street-railway motors have attained a national reputation for economy and general efficiency, with reference to the construction of an electric motor. The manufacturer at once exclaimed that it was useless for him to estimate on electric machinery,as he had found by experience that electrical people would not pay for the quality of workmanship that was required for proper locomotive running gear. What they wanted, he said, was a cheaper class of work, such, for example, as that used in a rather poor grade of agricultural implements.

This remark might well furnish a text for a very instructive sermon. If a locomotive is to haul a certain load over a given track, it is certainly very poor economy to use less perfect running gear for an electric than for a steam motor. Yet many electric motors which we have seen are eloquent witnesses to the truth of the remarks of the locomotive builder. And as if this were not enough, we have noted a certain disposition on the part of some electric-railway people to undertake what may be called feats of sensational engineering, such as running over imperfect tracks, and up and down impracticable gradients, and the like. There is no reason whatever to suppose that an electrically driven locomotive can run with safety where a steam driven one cannot, yet it is quite apparent that many people who ought to know better are being carried away with the delusion that any railway problem that presents peculiar difficulty can be solved at once by the application of electricity, just as we heard it gravely argued, during the prevalence of the narrow-gauge craze some years ago, that a locomotive of three feet gauge could ascend a steeper incline, other things being equal, than one of 4 feet 8½ inches gauge. We hear, for instance, of one line on which an attempt is to be made to work grades of over 700 feet per mile with electric locomotives, for passenger service. Unless special precautions are taken, as, for example, on the Mt. Washington or Mt. Cenis inclines, to undertake such a feat is to invite disaster.

The legitimate field which is now open to the electrically driven street-car is surely extensive enough without encroaching upon territory which legitimately belongs to the cable system. It is not good policy or good sense to make use of electric power in cases where it must compete, under unfavorable conditions, with directly applied steam power under favorable conditions. But this is precisely what is done, in effect, when we put inferior workmanship into electric motors, or when we attempt to use them in situations where an inclined cable system is obviously a much more safe and economical one.

ELECTRICAL LITIGATION.

THE year 1887 closes with a considerable amount of litigation going on in connection with electrical patents, although few, if any, cases of importance have been concluded during the year. At the time of writing, the Supreme Court has not delivered its decision in the Bell Telephone cases, although it has been anxiously expected for the last three months by the various parties in interest. The long delay would seem, if anything, to be an indication that the court will affirm the validity of the patents. If a sufficient defense were found among the many urged by the various defendants it would not be necessary to consider other points at length, whereas in preparing an opinion sustaining the patents, the court might consider every point carefully and at length, a proceeding, which in view of the enormous volume of evidence, would necessarily occupy much time.

The suit of the Western Union against the Baltimore

and Ohio Telegraph Co. for infringement of the Stearns condenser patent, is likely to be terminated by a decree by consent of defendants, a result which in view of the recent union of the two companies can hardly be said to be unexpected. It is reported that Mr. Van Hoevenbergh, late electrician of the Baltimore and Ohio, who was made a defendant to the suit, has not yet consented to the decree, a circumstance which may have the effect of prolonging the litigation.

The numerous suits brought by the Edison Electric Light Co. against the United States, Westinghouse, Consolidated, and other companies engaged in incandescent electric lighting, have apparently made but little progress during the year. In most of these cases the defendants have filed pleas, alleging that the Edison patents have expired, and that the present Edison company, which, it will be remembered, was formed by the consolidation of the original company with some of its sub-companies, has no legal standing in the present litigation.

The suit of the Thomson-Houston against the American Electric Manufacturing Co., alleging infringement of Professor Thomson's patent for automatic regulator for arc-light dynamos, is in progress, a considerable amount of testimony having been taken.

The suit brought by the Brush company against certain users of apparatus of the Fort Wayne Jenney Co. for infringement of the Brush arc-lamp patents, has been vigorously contested. The testimony has been completed, and the case, having been argued early in December, is now awaiting decision.

The suits brought by the United States Electric Lighting Co. against the Edison company alleging infringement upon Farmer's patent for regulating apparatus for multiple-arc circuits, are making slow progress, the testimony for the defense being yet unfinished.

Two suits have been instituted by the Westinghouse Electric Co. on the Gaulard & Gibbs patent for induction lighting by alternate currents, one against the Sun Electric Co. of Woburn, Mass., in which the evidence has been completed and the case prepared for argument, and the other against the United States Illuminating Co., of New York, in which no evidence has yet been taken.

Another action for infringement, which has been commenced but in which no evidence has been taken, is that of the Consolidated Electric Light Co. against the McKeesport, Penn., Light Co. This is a very important case, as it is designed to determine the validity of the Sawyer-Man patent claiming the exclusive right to the incandescent filament of carbonized fibre, which is employed by the Edison company as well as by most other manufacturers of incandescent lamps.

An action has also been commenced by the Brush company against the Faraday Carbon Co. of Pittsburgh, alleging infringement of Brush's patent for copper-plated carbons. A suit on the same subject was commenced by it some years ago against the United States company, but was dropped and never brought to an issue. A movement is said to be on foot among the manufacturers of carbon points to make common cause with the Faraday company in its defense.

Quite a number of other suits of minor importance are now pending in the courts in which electrical devices are involved, but the above list comprises the most important ones. It is probable that the present year will be marked by the decision of a number of important patent cases, which will have a marked influence upon the future direction of electrical development.

A TIMELY WORD OF CAUTION.

In a recently published article, a valued contributor pointed out in a forcible manner the dangers of ignorant engineering and of cheap construction in attempting to deal with the tremendous electrical forces which are coming into everyday use in connection with electric lighting and power distribution. It is impossible to lay too much stress upon this vitally important matter. No one who reads the daily journals can fail to have remarked the increasing frequency of fatal accidents from electric currents. At the same time nothing can be more certain than that almost without exception these casualities are due to the reckless manner in which unprotected conductors, charged with death-dealing electric currents, are placed in public thoroughfares, and in the vicinity of telegraph, telephone and other domestic service wires. We have no disposition to assume the role of alarmists in this matter; on the contrary, we are fully persuaded that with reasonable precautions there is no known agent for producing light or applying power, which in respect to absolute safety to life and property is comparable to electricity. But for this very reason it is all the more important that electricity should not receive an undeserved ill-reputation at the hands of its professed friends.

One need not go a thousand miles from New York to meet with flagrant examples of the dangerous practices to which we refer, while the too voluminous catalogue of accidents to persons and property reported from other parts of the country, show that the cause of complaint is not local but general. We referred some time since to some of the shortcomings of electric railway constructors in this direction, and are pleased to note that a marked change for the better is already observable. Nevertheless, it will hardly be credited that among the recently constructed electric street-railway lines is one in which the main electric conductors, designed to work with a potential difference of 500 volts, are extended for three or four miles, insulated from each other and from the earth only by the wooden poles, 100 or so to the mile, to which the conductors are secured by iron brackets only a few inches apart. Old electricians have not forgotten the exploits of the anti-insulation crank. They remember the competitive telegraph line which he built between New York and Boston, "before the war," and how he came to the front again in the local telephone service, and demonstrated that, the smaller the wire and the less the insulation, the better it served to convey the tones of the human voice, but they did hope that he would not attempt to carry out his theories with dynamo-electric currents. Nevertheless, he comes up smiling, as usual, but we shall try to keep an eye upon him.

While upon this subject, it is but a simple matter of justice to the Edison Electric Light Co. to say that from the commencement of its operations, it has insisted

upon and endeavored faithfully to maintain the highest standard of excellence in constructive details in the numerous plants which it has installed. Whatever of technical excellence is found in American practice, relating to electrical distribution, is unquestionably due in no small measure to the example set by this company, and to the influence of men who have received their training in its service. We want to see a like standard of excellence and safety extended to every department of electrical distribution, and shall use our best endeavors to that end.

THE TELEGRAPHIC SERVICE.

It is very hard to please some people. When the Baltimore and Ohio telegraphic system was purchased by the Western Union Company, a tremendous cry of "monopoly" was raised in the newspapers, and predictions were freely made that tariffs would be raised at once, in order that the public might be made to foot the bills for the telegraph war of the last three years. On December 2, a reduced schedule for a portion of its territory was announced by the Western Union, whereupon the anti-monopoly papers hastened to denounce this action with equal vigor as an attempt to head off any movement which the people's representatives in Congress might make to pass a government telegraph bill during the present session. Such a measure would unquestionably have the effect of converting the present surplus into a deficit, which seems to be one of the principal objects aimed at by a certain class of statesmen, but whether it would improve the telegraphic service is by no means so certain.

Notwithstanding the assertions to the contrary which are constantly reiterated by those who ought to know better, the facts are that the average charge per message has become less and less every year, and considering the distances covered and the facilities afforded, telegraphic service is cheaper in the United States to-day than in any country in the world. The Western Union report for 1887 shows that its average receipts per message amounted to 30.25 cents, being only half as much as it was no longer ago than 1874. It would be hard to point to a correspondingly great reduction in any other branch of public service.

In our opinion the ground of complaint lies wholly in another direction. The duplex, quadruplex, automatic, and other improved methods of working, have simply had the effect of reducing the cost of the service, and possibly of expediting it in some small measure. The result is that while the cost of sending telegrams is much less than formerly and the convenience greater, owing to the great number of offices and the introduction of the free "call-boxes" in the larger towns, there has been no very marked improvement in the celerity of the service, while in point of accuracy it has unquestionably retrograded. With the quadruplex and automatic apparatus, and the high pressure speed at which operators are now expected to work, there is far more occasion for "guess-work" on the part of the receiver and far less opportunity for inquiry and correction than formerly. Immature boys and girls, having no knowledge of general business, and with little or no sense of responsibility, are now preferred to the more careful and experienced operators of a former day, for the two-fold reason that they will "get off more business in a day" and do it for smaller wages. These causes, among others, have led to a distinct deterioration in the quality of the service. This deterioration manifests itself in two principal ways. One of these, the increased percentage of words erroneously rendered or misspelled, is patent to every one who makes extensive use of the telegraph, and the other, though less apparent is even more serious. We refer to the want of appreciation of the confidential character of the service. The old-time operator, even though, as in some instances he was, a tippler, a gambler, and little better than a vagabond, was rarely destitute of a certain professional pride, which ensured the sacred inviolability of every message that passed through his hands. We are now too frequently reminded of the greater laxity of modern methods by instances tending to prove, though of course not proving, the truth of the cynical adage, that "every man has his price."

What we would like to see is an increased sense of responsibility on the part of the managers of telegraph companies and of their employés, in respect to matters of this kind. There are large numbers of boys and girls in this city to-day, through whose hands pass business and social messages involving interests of the utmost importance, who never having had their attention called thereto, are utterly ignorant of the fact that it is a misdemeanor of the gravest character to give information respecting the contents, character or even existence of any particular telegram, a thing which ought to be impressed with all possible force on the mind of each and every candidate for a position in the telegraphic service.

In other words, let the telegraph operator, in this as in other particulars, be treated more like a rational human being and less like a mere attachment to a key and sounder.

The United States Electric Lighting Company announces through the columns of the *Western Electrician* that it possesses incomparably the best high tension alternating or secondary generator system extant, which is covered by fundamental patents, not used for advertising purposes but for the protection of its customers. It also cautions the public against parties posing before the public with "so-called alternating systems," and claiming rights under the Gaulard & Gibbs patent. We learn from this announcement that the last named system, having been found to be "impractical" has been abandoned, and that the parties referred to are infringing upon patents owned by the United States company, and are substituting such infringing apparatus for their own uncommercial and discarded system. If this is true, it is certainly much to be regretted. As the itinerant gospeller said, when denouncing the authorities of a certain town for the prevalence of immorality and crime in their bailiwick:—"And these proceedings are permitted to go on unchecked, in this *so-called* nineteenth century!"

An opportunity is now offered to those who invested in the stock of the People's Telephone Co., and who are tired of waiting for the decision of the Supreme Court at Washington, to put them, so to speak, out of their misery, which will enable them to send good money after bad, as the proverb has it. The sage of Yellow-Breeches Creek is reported to have evolved an invention which renders the softest footfall audible at a distance of many miles, and is confidently expected to put an end to the reprehensible practice, common alike in rural and urban communities, known as "bein' out o' nights." He might next turn his attention to inventing something or other for the benefit of that somewhat numerous class of the community, which "don't know enough to go in when it rains," and which has aided so liberally in bringing his previous achievements to the notice of a discriminating public.

ARTICLES.

TRANSMITTING SPEECH BY INTERRUPTED ELECTRICAL CURRENTS.

BY C. J. KINTNER.

(Late Principal Examiner Class of Electricity, U. S. Patent Office.)

(Continued from page 468.)

The contact telephone which depends for its mode of operation upon the variation of the actual contact surfaces between the electrodes, differs from the magneto instrument in that, the currents always move, so to speak, in one direction, there being only a rise and fall or change of volume due to a constant electromotive force or tension and a varying resistance, the effect on the receiver being the equivalent of the reverse currents, which arise in a magneto transmitter.

A diagram representing the current waves of such a transmitter will therefore be unnecessary, it being understood that such a diagram would show simply increased and decreased volumes for the overtones and fundamentals due to a current of constant electromotive-force where the diaphragm in figure 2 shows increased currents, decreased currents and reversals. (See the ELECTRICAL ENGINEER, vol. 6, No. 72, p. 467.)

Figure 1 represented diagrammatically the volumes of current for a pure musical tone when uttered into a Bell magneto instrument.

The composite tones differ in the main only in degree from the pure tones, and if the instrument be so modified as to meet this change of degree it will meet all the requirements necessary to transmit such composite tones. Very much has been said during the telephone controversy of tone quality and its two companion elements, pitch and intensity. It has been urged with good success, that there is an absolute necessity in the transmission of articulate speech that the timbre or tone quality be transmitted, but so far as I am aware it has never been pointed out that this tone quality is purely a matter of degree; that the voice of one person differs from another only in degree of musical purity, and that the instrument which will transmit one voice will not successfully transmit another in all its purity.

It has been the argument of the learned counsel in the Bell suits, that it was absolutely necessary that the transmitting diaphragm should so mould the electrical currents on the line as to create actual copies in the receiver at the distant station, and the magneto instrument does it beyond a peradventure of a doubt. This argument is undoubtedly correct for telephones of that type.

If, then, as I have asserted, individual voices differ from each other only in their degree of musical purity, and no one can doubt it who has listened to the smooth liquid voice of the Italian or Frenchman as compared with the guttural hoarse voice of the German; if such be the case, and if the Reis instrument transmits pure tones by current impulses of constant volume, then why cannot this instru-

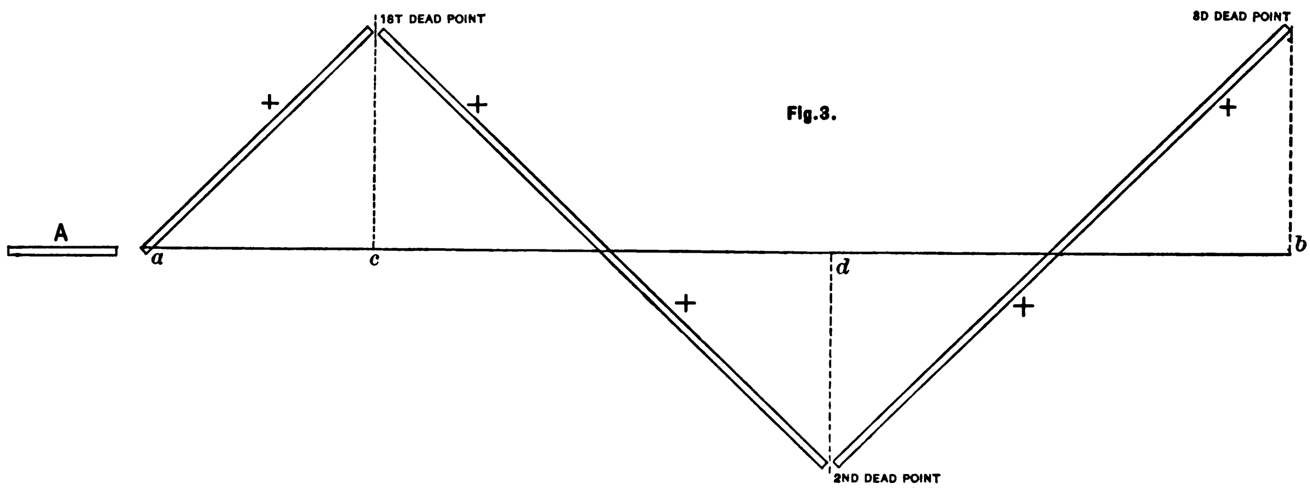

Fig. 3.

Figure 3 represents the same for a Reis transmitter, *a*, *b*, being the medial line of the diaphragm at rest, and A the volume of current flowing under all conditions. In a word, as there are no overtones and the beats or vibrations are regular, the electrodes being of hard metal as iridium, there will occur at the fundamental and sole dead points of the diaphragm, breaks in the current in regular recurrence.

A constant volume of current will flow for all phases of the diaphragm equal to A, and electrical impulses will be set up over the line of equal volume and duration which in turn will actuate the receiver and cause it to repeat accurately this fundamental tone. It is not possible that there can be current variations between absolutely clean hard iridium contacts, for the individual molecules are so small or so compact that for the infinitesimally small power of a delicate pure musical tone, such a proposition is absurd. I think, however, if proof be demanded, that such pure tones are transmitted otherwise than by individual current impulses, the Gray system of unison reeds will substantiate it.

If, then, a pure musical tone can be transmitted by current impulses, why cannot composite tones? What is the difference between these two classes of tones that one can be transmitted by the Reis instrument, while the other cannot?

ment be so adjusted as to transmit such composite musical tones; and has it not been done in the past by scientists unconscious of the actual mode of operation? It is, I think, generally admitted that speech can be transmitted by the Reis transmitting apparatus, but it is urged that the Bell method is practiced whenever such result is attained; that there has been current variation between the electrodes rather than actual makes and breaks, and much has been said about continuity of contact through the spark if actual mechanical separation took place between the electrodes.

In figure 4, I have shown a diagram of the current impulses created in a Reis transmitter when adjusted to transmit the same composite sounds shown by the diagram in connection with a Bell magneto shown in figure 2 (see ELECTRICAL ENGINEER, vol. 6, No. 72, p. 468). *a*, *b*, represents the medial line of the diaphragm as before, and A the current volume.

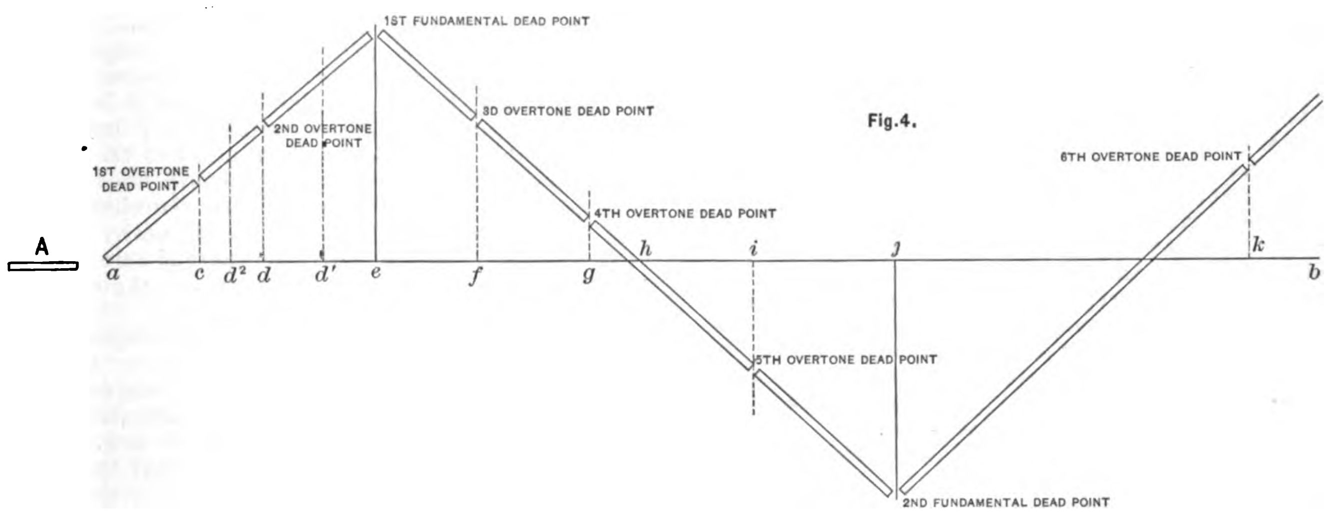
The diaphragm is under stress and is tuned to a given pitch, that of the normal voice of the speaker, and the movable electrode is a weighted lever adjusted to vibrate in absolute unison with the diaphragm under all conditions. That is to say, if the diaphragm makes 200 vibrations per second, the loose electrode of pendulum form will vibrate absolutely with it, separating from it only by virtue of its inertia, as the diaphragm tends to recede from it at the

reverse overtone and fundamental dead points. As a result we have actual mechanical separations at *c* and *d* for the first and second overtones and at the first fundamental. There will be no separation for the advance overtones or such as increase or aid the fundamentals, and hence these overtones will be lost. It is true the speech may be somewhat mutilated, but for all overtones where the tendency is to decrease the fundamentals there will be a separation of the electrodes and the receiver will be affected thereby, the current volume always remaining constant and the impulses copying the reverse overtones.

It may be urged that if we neglect the advance overtones, or such as aid the fundamentals we neglect much of the transmitting current impulses, and hence mutilate the speech so as to make it more or less unintelligible.

Such is not the case, and I am convinced that with existing contact telephones it is only the action of such tones as actually check the advance of the diaphragm that gives the actual tone qualities, and that the advance, or aiding overtones, do little to modify the tones in the receiver.

The instrument used by me in my experiments consisted of a rectangular diaphragm about three inches long by two and one-half in width, held at its ends by means for regulating its tension; near its centre was a polished steel electrode. This diaphragm hung in its frame so as to adapt it to be adjusted to any angle. The loose electrode of hard steel hung from pivots like a pendulum and was provided with a pendulum bob for adjustment. By adjusting the diaphragm to a given pitch and the weight or bob on the loose pendulum electrode so that it would vibrate in unison for a given note, I found that on uttering the word "hello," into the instrument, only unintelligible disagreeable sounds were heard until I struck the key to which the diaphragm was tuned, when the attendant heard it very plainly and continued to hear it until the pitch of my voice was changed, when only confused sounds were again heard.



If the apparatus operated by the Bell method, why would it not operate when the voice was pitched in a different key? There can be but one solution of the problem, and that is, that the electrodes vibrated in unison with the key note of the voice, separating for all the radical phases of its overtones and fundamentals. It is absurd to suppose that there can be such a phenomenon as current variation due to pressure between two hard polished steel electrodes under pressure of so delicate a force as the sound waves of the human voice, as it is equally absurd to suppose that there lies in the spark, if a spark does in fact exist between such electrodes when separated, an inherent self-acting force which so modifies the electrical currents as to make them of a wave or undulating nature. With a delicate microphone transmitter having variable contact surfaces, as in the Hunnings instrument, such a thing is admissible and entirely in harmony with the operation of the magneto apparatus, for in such an instrument there is clearly a change of conductivity due to this change of pressure.

Whether or not such a contact telephone as I have described is practical, is another question which need not be discussed here; the simple fact that with such an instrument intelligible speech can be transmitted by current impulses being the question under consideration. That it does it, and in the manner described is clear, and that the Reis instruments, wherever operating to transmit speech, do it similarly, is also, an undoubted fact in my opinion.

PHENOMENA OF RETARDATION IN THE INDUCTION COIL.[1]

BY WM. STANLEY, JR.

This paper will attempt to emphasize the time relations of the alternating E. M. F.'s. and currents in the induction coil. Any description of the phenomena of retardation accompanying the inductive effects of currents would necessarily be incomplete and unintelligible without a clear conception of the fundamental principles of the induction coil. This must be my excuse for briefly recalling to you the rudiments of the induction system.

An alternating E. M. F. differs from a direct E. M. F. in two important points: It varies continuously, and its direction or polar tendencies alternate.

To illustrate graphically the various values of an alternating E. M. F. and the attending phenomena, it is usual to plot a series of curves above and below a straight line.

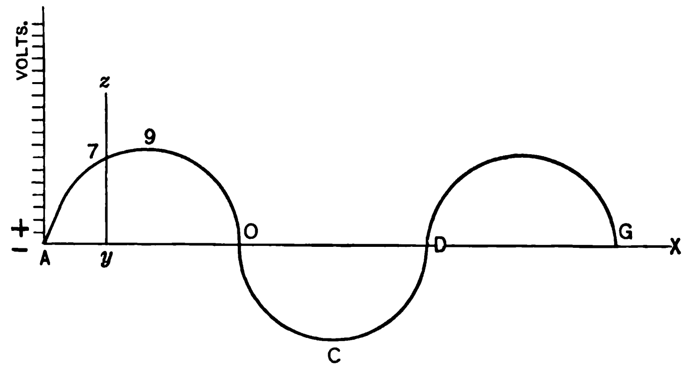


Fig.1.

This line, when divided in equal divisions, may be taken to represent successive periods of time, as in figure 1. Starting at the point A, the E. M. F. is seen to rise rapidly above the line A X in a gentle curve (the particular curvature of

1. Read before the American Institute of Electrical Engineers, New York, Dec. 6, 1887.

which depends on the construction of the generator), until at 9 it reaches its highest point; thence it flows downward in a similar but reverse curve, until it again reaches the line A X, and, continuing downward, finally attains a sub-maximum at C. From this point it rises again, crossing the line A X once more at D, whence a repetition of the former curves occur.

The E. M. F. of the alternating current at any particular time can be determined by the distance of the curved line above or below A X at that time. For instance, suppose we wish to determine the E. M. F. at any time, y. Through y draw $y\ z$ perpendicular to A X, cutting A 9 at 7. Then 7 y represents the E. M. F. applied to the circuit at the time y.

From an examination of the curve it will be seen that at stated intervals of time A, O, D, G, there is no E. M F. applied to the circuit; and, if the curves above the line A X

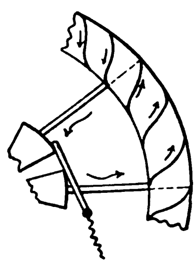

Fig.2.

represent E. M. F's applied in one direction, those below the line A X represent E. M. F.'s in the opposite direction. Hence adjacent E. M. F's alternate in direction, and hence the term alternating currents.

There is a general misunderstanding to the effect that the alternate current dynamo is less economical than is the direct current generator. This is not so; there is a little difference, it is true, but the difference is, I believe, in favor of the alternate current machine. Let us take a dynamo field, for example, that of a simple direct current type of dynamo, and separately excite it with a constant current; let us now wind two armatures of identical dimensions, one for direct and one for alternate currents, and arrange to run them at the same speed; and let the windings of the two armatures be identical in size and number of turns of wire. Now the E. M. F. produced in these two armatures will be found to be, for the direct current armature:

E. M. F.	X volts.
Resistance of the armature.....	R ohms.
Amperes per section of winding...	A amperes.

And because the armatures are identical we have for the alternate current dynamo:

E. M. F.	2 X volts.
Resistance of armature....................	4 R ohms.
Amperes per section of conductor	½ A amperes.

Thus the direct current dynamo will generate A X watts, and the alternate current dynamo $2\ X \times \frac{A}{2}$, or A X watts, also. Hence the capacities of the armatures are equal.

The loss of energy in the armatures will be, for the direct current dynamo, $A^2\ R$ watts. For the alternate current dynamo $\left(\frac{A}{2}\right)^2 \times 4\ R$, equals $\frac{4\ A^2\ R}{4}$, or $A^2\ R$ watts. From this we learn that the losses in the armatures are equal. It is stated, however, that owing to self-induction, Foucault currents, or something else, these figures do not represent the actual waste of energy. The waste of energy by self-induction in the direct current dynamo occurs when a brush on the commutator touches two adjacent strips at the same time, as in figure 2. The arrows indicate the direction of the induced currents, and show that at that time all the E. M. F. of the short circuited coil is wasting current on a short circuit through the brush. What now is the loss in the alternate current dynamo through self-induction?

In the direct current dynamo the current flowing through the armature coils magnetizes the armature with a polar line at an angle to the polar line of the field. These armature poles maintain a constant position relative to a fixed point, and are of a constant value. In the alternate current dynamo, the current in the armature rises above and falls below a zero value periodically; hence the iron in the armature has periodic polar tendencies at an angle to the polar line of the field.

I shall endeavor to show that instead of wasting energy by periodically polarizing the armature, the E. M. F. devoted to this purpose is at first temporarily stored and subsequently returned. As is well known, a certain period of time is required to establish a given magnetic charge in iron, which time is directly proportional to the degree of magnetization to be attained. If, therefore, we plot a curve, the abscissæ representing time and the ordinates the degree of magnetization, and if we apply this curve to the curve of E. M. F. producing it, we have two similar curves separated from one another by a given period of time, as shown in figure 3, where 1, 2, 3, 4, 5, represents the curve of E. M. F., and 6, 7, 8, 9, 10, the corresponding curve of magnetization.

When the coil on the alternate current armature leaves a pole of the field during rotation, the lines of force threading it rapidly diminish, and by induction generate an E. M. F. in the coil. The rise of E. M. F. and consequent flow of current in the coil is attended by a magnetic polar effect in the iron core, which not only increases while the E. M. F. is rising from 1 to 2, but continues to increase, attaining its maximum value when the E. M. F. has fallen to K. Up to this time, namely, the time when the magnetic charge is maximum, energy has been expended upon the iron core; but notice, that at this time the charge on the iron core is superior to the charge producable by the E. M. F. at that instant; consequently, the charged core does positive work upon the E. M. F., if I may use the expression, and in doing this decreases its own value.

This auxiliary E. M. F. developed by the magnetized core upon the armature conductor assists the E. M. F. proper; that is the E. M. F. developed by the field magnets. Thus the energy devoted to magnetizing the armature, during the rise of wave of E. M. F., is returned as E. M. F. during the fall of potential. We may assume that the wave is

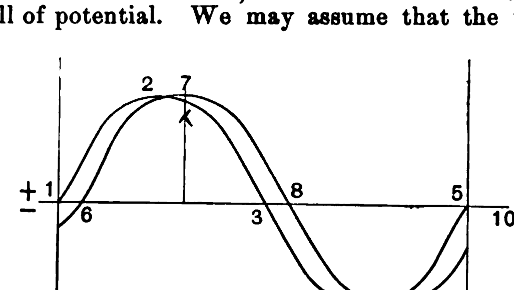

Fig.3.

shifted along or retarded. Figure 3 illustrates this retardation. 1, 2, 3, 4, 5, is the curve representing the position of a wave of E. M. F., without taking into consideration the effect of the iron core, while 6, 7, 8, 9, 10 is the curve-wave of E. M. F. which has been retarded, by reason of the magnetic charge on the iron from the theoretical position, 1, 2, 3, 4, 5.

The curve of E. M. F. of a coreless armature is quite different; here, as before, the theoretical curve is A, B, C, D, E, figure 4. Let us see what the effect of self-induction is in this case.

We know that self-induction is proportional, among other things, to the current flowing at a given time. Now, at the time A, no current flows; hence, there is not self-induction. But as the E. M. F. rises, and the current is driven

through the coil, the self-induction or counter E. M. F. prevents the E. M. F. from attaining its theoretical value. It does not delay the E. M. F. from its theoretical time position, as is the case with an iron core, but prevents the E. M. F. from attaining its theoretical maximum value at any time. The real curve of E. M. F. in this case would be A, G, C, H, E, figure 4. This curve shows that there is no waste of energy due to counter E. M. F., but that the armature output is reduced by self-induction. An iron core, therefore, causes the counter E. M. F. to oppose the E. M. F. proper only during one-half a period, and allows it also to assist the E. M. F. proper during the other half period in the phase.

It is evident that the time of retardation, viz., the distance between 1, 2, 3, 4, 5 and 6, 7, 8, 9, 10, figure 3, de-

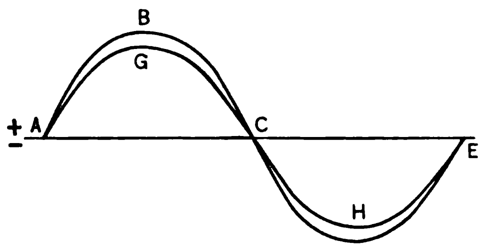

Fig.4.

pends on the quantity of current flowing through the armature coils as well as on the core. I have described this point at length, as there is a general, although false, impression that the iron core of an alternating armature necessarily wastes energy.

We may roughly compare the theoretical efficiencies of the direct and alternating dynamos, as follows: The output is equal; the waste of energy in armatures due to c^2 R is equal. The waste due to self-induction is greater for direct than alternating dynamos, with properly constructed iron cores.

Faraday's law of induction may be stated as follows: The variation of the magnetic field surrounding a conductor induces an E. M. F. in that conductor. A variable field is produced by a variable current, and hence, a conductor carrying an alternating current will induce an E. M. F. in another conductor residing in the same field.

Let us note the values of the E. M. F.'s in the inducing or primary, and induced or secondary circuits, at the same time, and first when no current is flowing. The curve, A, B, C, D, E, figure 5, represents, as before, the alternating applied E. M. F. Now, the induced E. M. F. will be a maximum at the time when the inductive effect of the primary current is a maximum, and the inductive effect of the primary will be greatest when its E. M. F. is changing most rapidly. Evidently this will occur near the zero line A X; for the E. M. F. will vary greatest when passing from a finite value to zero, or from zero to any finite value. Hence the inductive effect of the primary and the E. M. F. developed on the secondary circuit will be a maximum when the primary E. M. F. is least.

Figure 5 represents the time relation of the primary and secondary E. M. F.'s when no current is passing. The position of maximum E. M. F. of the secondary is, as you see, one-fourth of a complete period behind that of the primary. Now, a moment's consideration will show that the secondary circuit is simply the receptacle of an E. M. F., and, when no current is flowing in it, plays no part in the inductive phenomena.

The primary circuit evidently will induce in itself an E. M. F. in the same manner that it impresses the E. M. F. on the secondary circuit. Hence, in any circuit to which is applied an alternating E. M. F., we have two phases of E. M. F.; the one, the applied; the other, the self-imposed; the points of equal value in each being distant from each other one-fourth of a complete period, when practically no current is flowing. This self-impressed E. M. F. is called "self-induction," or counter E. M. F. When two or more coils are wound together so as to act collectively, the effect of the one upon the other is termed "mutual" induction. We now see why, when an alternating E. M. F., of, say, 1,000 volts, is suddenly applied to a coil whose resistance is low, as, say, 1 ohm, the coil does not receive the quantity of current destined for it by Ohm's law. The kinetic E. M. F. is very small, because it is the difference between the applied and counter E. M. F.'s.

Figure 6 shows a wire wound on itself or coiled. The full arrows indicate the direction of the applied E. M. F., the dotted arrows the counter E. M. F. In the two adjacent turns one impresses a counter E. M. F. on itself, and also a counter E. M. F. on the other and the other impresses a counter E. M. F. on itself and on the former. Hence in two coils of wire we have four impressed counter E. M. F.'s. This is commonly stated as the self-induction, and is proportional to the square of the number of turns.

We will now consider the time position of the currents flowing through coils impelled by the E. M. F.'s of which we have spoken, and endeavor to apply the effects of the various positions they assume to a few of the phenomena noticed in working induction coils with different current strengths.

Evidently, when little current is flowing over a conductor, the self-induction and retardation are small; hence the curve of the current nearly coincides with the curve of E. M. F. Figure 7 illustrates the positions. Here the phase of the primary current nearly coincides with the phase of its E. M. F. The curve of the secondary E. M. F. is, however, just one-fourth of a period later than the primary current phase, while the curve of the secondary current is still farther behind it; so that, while the primary current phase is x distance behind the primary E. M. F. phase, the secondary current phase is 2x plus one-fourth of a period behind the primary E. M. F. phase. This delay reacts on the primary E. M. F. The lower curve in figure 7 is the curve of the counter E. M. F. developed by the

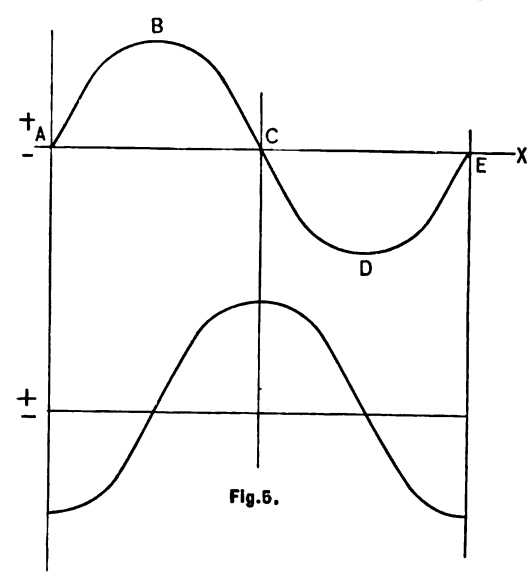

Fig.5.

secondary current upon the primary circuit. It will be noticed that it no longer exactly opposes the phase of the applied E. M. F., for the time line AB, passing through the maximum position of the primary E. M. F., cuts the counter E. M. F. curve at a point before its maximum value is attained.

Figure 8 shows an extreme case. Here the curve of the primary current is one-eighth of a period behind its E. M. F. Consequently, the curve of secondary current is one-half a period behind the primary E. M. F., *i e*, $\frac{1}{8} \times 2 + \frac{1}{4}$; and the curve of counter E. M. F. developed by the secondary current is $\frac{3}{4}$ of a period behind the primary E. M. F.

We are now prepared to understand why the counter E. M. F. developed in the induction coil varies in its counter effect as current is abstracted from the coil The reason is simply that its position of counter effect is dependent on the curve of its producing current, and as the current occupies a variable position relative to the applied E. M. F., the counter E. M. F. successively occupies positions of lesser counter effect until eventually it has no counter effect whatever.

These phenomena are taken advantage of in the operation of induction coils. If a constant E. M. F. be applied

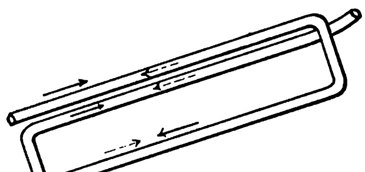

Fig.6.

to the primary circuit of a converter, successive increments of current will be allowed to occupy this primary circuit, as successive quantities of current are abstracted from the secondary circuit; because these currents push along out of the way the opposing counter E. M. F., and consequently the kinetic E. M. F. attains correspondingly greater values.

Thus far we have considered only two factors of self-induction and retardation, viz., the number of turns of the conductor, and the quantity of current flowing; but there is another factor, most important, and that is, the resistance of the magnetic circuit.

The magnetic resistance of iron is, as you know, similar to the resistance of any other conductor, in that it is directly proportional to the length, and inversely proportional to the sectional area of the circuit. This, however, is only true for limited values of magnetism. As the magnetic lines traverse a core they encounter a resistance proportional to their number at first; but if more lines be continuously

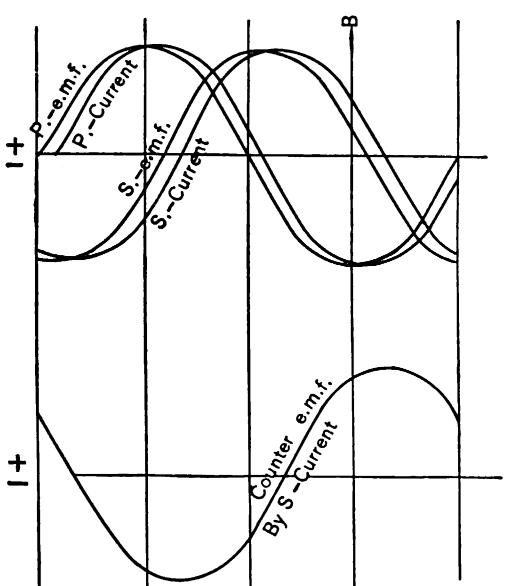

Fig.7.

added, a number is eventually reached which the iron utterly refuses to carry. This degree of magnetism is termed "saturation."

It can be shown that the position of the curve of counter E. M. F. is directly connected with the degree of saturation of the core, so that with a given coil the position of no counter effect of the counter E. M. F. coincides with saturation of the core. The magnetic resistance of the core of an induction coil determines, then, the limit of retardation or lag of the current phase. Hence, if we wish to construct a coil in which the counter E. M. F. shall always be inversely proportional, and the kinetic, applied E. M. F., always directly proportional to the current abstracted from it, we make the core of the coil with the lowest possible magnetic resistance. Such a coil, when supplied with a constant difference of potential, will furnish at its secondary terminals an approximately constant E. M. F. It is also evident that a coil having a limited section of core supplied with a constant current may deliver a constant

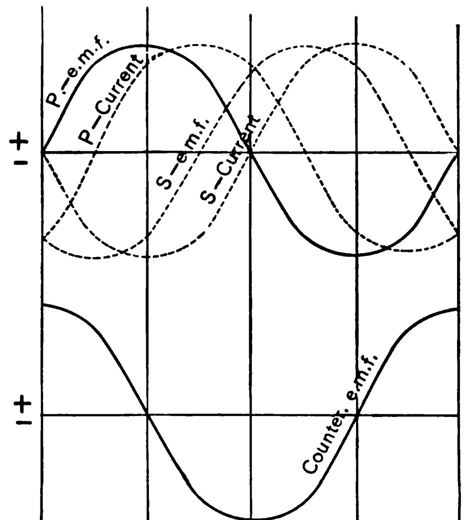

Fig.8.

E. M. F. on its secondary terminals, provided the field produced by the constant current is sufficient to saturate the core.

I noticed these phenomena several years ago when experimenting with a series system for lighting. Mr. O. B. Shallenberger has applied this saturation effect in a most striking manner. He connects a number of incandescent lamps, say four, in series attaching their outer terminals to a source of constant alternating E. M. F. (figure 9). Around each lamp is shunted a self-induction coil, so proportioned that an E. M. F. of say 100 volts will saturate the

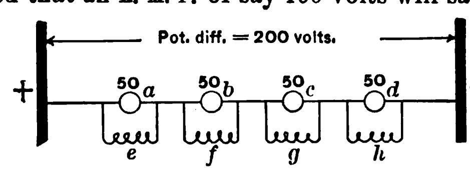

Fig. 9.

core of the coil. If, now, a lamp be turned off, its current is diverted through the shunted coil, which offers a counter E. M. F. of 100 volts. We would naturally expect that the light in the remaining lamps would grow dim, but this is not the case. If we measure the difference of potential on the extreme terminals of the lamps we find it to be 200 volts; on the three burning lamps it is 50 volts each, while on the shunted coil it is 100 volts; so that the sum of the potentials of the three lamps and the coil is 250

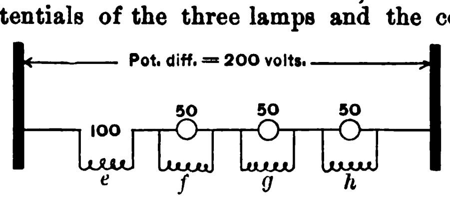

Fig. 10.

volts, while the applied E. M. F. is but 200 volts (figure 10).

I think the explanation of this is as follows: During the first part of the rise of the E. M. F. wave, the shunt coil practically offers an infinite counter E. M. F., in comparison with which the resistance of the lamp may be neglected; when, however, the applied E. M. F. has attained a value of 100 volts, this counter E. M. F. is surmounted, because the core of the coil is saturated by the current flowing in the coil.

The lamps, therefore, receive the remaining 100 of the

200 volts applied, since the coil, being saturated, offers no additional counter effect. Now, after the wave of E. M. F. has declined to a value less than 100 volts, the stored magnetism in the core of the shunted coil begins to lose strength, and in so doing, develops an additional E. M. F., which, assisting the generator current, furnishes a current during the time the applied E. M. F. is of low, or zero, value, and by so doing keeps the average E. M. F. on the lamps constant.

It is necessary then, in working with alternate currents, to take into consideration the time retardation or lag of the current behind the E. M. F. We have seen that this lag is dependent on the resistance of the core, and on its degree of magnetization. I have found it especially necessary to make time corrections in work on alternate current motors, and in apparatus depending on the attraction or repulsion of magnets energized by alternate currents.

I have stated that there is no loss due to the periodic magnetization of iron cores by an alternating current. This is only true of a perfectly subdivided core. A solid core allows secondary currents to flow. Hence its storage capacity is lowered. In practice, the loss due to wasted currents in laminated cores can be kept as low as one per cent.

We may summarize the effects of the retardation of currents behind the E. M. F's. in the induction coil as follows:

Retardation causes the counter E. M. F. developed to have counter values inversely as the quantity of current flowing in the coil.

Retardation causes the energy expended in magnetization during the increase or development of a current to be returned as current energy during the subsidence of the current.

To an alternating or similar current, iron offers true storage capacity for all values of magnetization below the saturation limit.

REVISION OF THE PATENT LAW.[1]

BY ARTHUR STEUART.

General Counsel of the National Electric Light Association, Baltimore.

I COME before you this evening at the invitation of your secretary, for the purpose of telling you of the effort that is being made by the National Electric Light Association to secure some reforms in the patent laws of this country, and of attempting to get you to join hands with us in carrying these reforms into effect. I particularly desire that the suggestions I shall make may be fully discussed by those present, for I hope to gain many valuable suggestions from you. For the purpose, therefore, of presenting what I have to say in the shortest possible time, so as to leave as much as possible for other gentlemen, I have condensed my suggestions and shall state them with very little argument; first, for lack of time, and, secondly, that I think most of the reforms suggested are so apparent that they will call forth little opposition. But, before proceeding to discuss the details of the law that require changes and additions, I cannot refrain from making a few remarks upon the patent system in general and its influence upon the industrial development of our country. Who can measure the benefits that this land has derived from the inventions that have been produced by its citizens? The roll of honor is too long to be repeated. The cotton gin, the printing press, the reaper, the application of steam to all the uses of civilization, and, latest, but not least, the modern application of electricity in its multitudinous forms; but while these brilliant achievements occupy our attention, we must not overlook the thousands upon thousands of inventions relating to matters of detail in every industry that have cheapened the product by saving time, material, power or labor. The fact is apparent that our advancement as a manufacturing nation has been due to the introduction of new methods of work which have enabled us to produce staples at such a price as to compete with other nations in the markets of the world or in the development of new devices which have supplanted old ones or created a market for themselves. This being true, we must look for a cause for this development. What has induced the people of this country to create so many new things, to labor so long and arduously to lessen the cost of production of some articles, or to supply a new one to take its place which is better or cheaper?

I think we may state it as a proposition that will not meet with denial, that the prevailing motive of the American people is a motive of pecuniary gain, a desire to amass wealth, to attain power by means of money, and whatever avenue offers them this reward will be the one into which they will press with a vigor and determination that knows no such thing as failure.

When the framers of our constitution inserted into it the clause which provides that "Congress shall have power to promote the progress of science and the useful arts by securing * * * for limited times to * * * inventors the exclusive right to their * * * discoveries," they laid a foundation stone upon which an edifice has been constructed that has far surpassed anything they had conceived. Upon this provision of the constitution is our patent law based, from it it takes its spirit, and with the view of adhering more closely to this spirit have the amendments to the patent law been suggested to which I shall ask your attention this evening.

The patent laws of the United States passed in pursuance of this provision of the constitution open up before every citizen of this country, as well as before those of many others, opportunities of obtaining wealth and power that are not presented by any other set of circumstances under the sun. In a single moment of time by a quick operation of the mind the poor mechanic may be put into possession of an idea that by its own development may place him among the princes of the land.

This is the possibility that presents itself to every man, rich or poor, high or low, who comes to understand the meaning of our patent system and its results.

What force can be compared with this to produce in the minds of men, thought, deep, concentrated and continuous, for the production of inventions, a thirst for knowledge and a frugality of life that will supply a surplus of funds for the acquisition of knowledge and the development of inventions, and an ambition for their children that they shall have greater advantages of education upon which to work than their parents? And who can estimate the value to a state of such influence upon its citizens. This training, foreign manufacturers testify, produces in American operatives a power of comprehending their work and a rapidity and dexterity of workmanship that makes it impossible for them, with labor at one-half the cost, and their factories fitted with the latest American machines, to produce the same goods as cheaply as they can be produced in this country.

It therefore goes without saying that with such an inestimable good to the nation, both in improving its industries and its people, to be attained by stimulating inventors to their highest effort, the only true course for the law makers to pursue in framing legislation relative to this subject, is to endeavor to make the process of obtaining a patent upon an invention as quick, easy and inexpensive as possible, and after it is granted to throw around it in the hands of its owner every form of protection known to the law, that will enable him to realize the full intent of the constitution and enjoy the exclusive right to make, use and vend the invention.

Our patent system as it exists to-day is a grand structure, but it has some defects which are due principally to the fact that the demands made upon it by the development

1. Read before the American Institute of Electrical Engineers, New York, Dec. 20th, 1887.

of our industries have far exceeded anything that the framers of the present law contemplated.

The patent law of to-day is substantially identical with the law passed by Congress in 1836. This law was revised in 1870, and codified in 1874, but few changes were made in it, and little if any provision was made, to accommodate the immense mass of business that has been cast upon the Patent Office, and some of the new features that were introduced have been found to work a hardship upon inventors rather than a benefit. So that practically we are working under a law formulated 50 years ago, when the work of the Patent Office for the whole year was something less than it is to-day for each week. Is it surprising, therefore, that the child should have outgrown his clothes? And this is practically just what has taken place. A commissioner and a half dozen examiners were quite equal to the task of examining intelligently 450 patents a year, but the case is a very different one when the commissioner has under him something over 200 examiners, and when the annual issue of the office is something over 25,000 patents.

If time permitted, I would show you how utterly impossible it is for the work of the Patent Office to be accomplished with any degree of satisfaction to the public under the prevailing organization, but I know that most of you are quite as well aware as I am of the defects that exist, and are quite as much interested in removing them. I shall pass at once to the consideration of the measures of reform that seem desirable in the Patent Office.

I.—THE PATENT OFFICE SHOULD HAVE THE EXCLUSIVE USE OF ITS BUILDING.

All those who have had any experience with the internal operations of the Patent Office are aware of the fact that this office is greatly cramped for space. The examiners are often crowded into rooms that are so small that there is scarcely space enough between the desks to move about. Many of the officers and employés are compelled to work in quarters that are unfit for human habitation, simply because there is no other place to put them; and the documents and records of the office are so crowded, and the places in which they are kept are so unfit for their accommodation that they are in constant danger of destruction. The Patent Office building was constructed with money every dollar of which was paid to the government by patentees and applicants for patents, and yet the Patent Office is crowded into less than half of this building. The interior department, with its land office and Indian department, occupy the balance.

The interior department should have separate quarters and the Patent Office should have the whole of its building, which will not more than accommodate it.

II.—THE PATENT OFFICE SHOULD HAVE THE WHOLE OF ITS OWN INCOME.

For the past 50 years the Patent Office has paid all of its own expenses, has built its own building, and in addition to this has paid the government an annual revenue which aggregates to-day, without interest, something over $3,000,000. And yet the most difficult task that the commissioners of patents have had to perform has been to induce Congress to authorize the expenditure of a part of this revenue for the necessary expenses of the Patent Office. For the proper despatch of the work of the Patent Office considerable additional force is necessary. The commissioner of patents should be authorized to expend the whole of the income of the office for its own expenses, and what was not spent should be set aside as a fund to be used for the benefit of the office at any time that it is needed.

III.—EXAMINERS.

The staff of examiners in the Patent Office have charge of public interests of a most vital nature. They are the virtual judges of whether an inventor shall have a patent for his invention at all, and also of what kind of a patent he shall have in case they give him any.

It is therefore apparent that in order that they may perform their duties with intelligence and efficiency they must fulfill several conditions:

1st. They must be thoroughly educated in the technology of the arts and sciences and in the patent law. Experience has shown that this training can only be acquired in one of two ways, either by systematic teaching or by years of experience in the practical work of the Patent Office; the latter method is the one now in operation, and it results in creating a class of examiners who are undergoing the process of education at the expense of the unfortunate inventor whose case may fall into their hands. The inventors of the country have a right to demand that this system of education of examiners at their expense be discontinued and a system adopted that will secure to the Patent Office a corps of examiners who will be thoroughly trained before they enter the office, and to the inventor the examination of his case by a man fully equipped to make such examination in the best manner.

2d. Having obtained a staff of competent and thoroughly equipped examiners, they must be retained in office, so that the public may have the benefit of their services through a number of years. The army and navy have long since solved this problem by the exercise of a system of education, compensation, promotion and retirement on pay which fully secures these ends. Why should not that system so successful in one branch of the government service be established to secure similar and equally necessary results in the Patent Office?

3d. The examiners should be relieved from all political influence. Civil service reform has attacked the question of political interference with Patent Office appointments with little success. The evils from this cause now existing are great and call loudly for remedy. The army and navy system has put those departments of the public service almost entirely beyond the reach of the politicians. Thus it should be with the Patent Office.

IV.—SALARY OF COMMISSIONER OF PATENTS.

The salary of the commissioner of patents should be very high, so that every examiner may feel that if he is faithful and does his duty he may some day, in the natural order of promotion, reach a place of honor and large emoluments. This is the system of the army and navy, and in those departments it works admirably.

V.—A PATENT COURT SHOULD BE ESTABLISHED.

The greatest evil that exists to-day in the administration of the patent system, lies in the lack of harmony between the Patent Office and the courts of the United States in which infringement cases are determined. Every practitioner before the Patent Office knows how little regard is paid by the examiner to the decisions of the courts upon questions of patent law, and it has long since become a thing of the past when the courts give any weight to the presumption of patentability that would naturally arise from the fact of the commissioner of patents having granted a patent upon a device. For the accomplishment of the best results with our patent system, the interpretations and application of the law under which patents are granted should be the same as that under which rights growing out of patents are determined. So that a right granted by the Patent Office would be sustained by the court, and the rulings of the courts would be in conformity with the spirit of the constitution which has originated the whole system.

Under the existing system the examiners in the Patent Office interpret the patent law for themselves, and it has been my experience that few of them agree upon many points. The practical questions which have to be passed upon by the examiners seldom if ever get before the circuit courts, but are decided by the commissioners of pat-

ents, who, it is well known, seldom possess any knowledge of patent law when they enter upon the duties of the office, and seldom occupy the position long enough to be of any practical service to the office after they have learned something of the law by experience. The result is that a majority of the cases passed upon by the commissioners, and which are intended for the guidance of the examiners, are decided at a time when the particular commissioner is almost entirely ignorant of both the law and the practice of the office. It is, therefore, only to be expected that the examiners should form their own notions of the law and pay little regard to either courts or commissioner, and as the examiners are not lawyers and have no knowledge of the patent law, except such as they may gain from the conflicting decisions of the ever changing commissioners, and as they have had no judicial training, it follows as a matter of course that each primary examiner has his own interpretation of the law and his own peculiar notions of how it should be applied to the practical questions that arise in his daily work. The result is that we have as many different patent offices as we have divisions and scarcely any two of them with the same views of the law, but each having the power and exercising it, of issuing patents according to his own individual notion of what the patent should contain and how it should be framed, and these patents thus issued are the title papers upon which the inventors of the country are compelled to base their claim when they come into the courts for the purpose of protecting their property. Is there any wonder that it is difficult to obtain a patent of any value or to sustain and protect it after it is procured? It seems, therefore, to be eminently desirable that the same tribunal (which shall be so framed as to insure its capacity) should have appellate jurisdiction from both the Patent Office and the circuit courts, so that by vesting both jurisdictions in one competent court, the rulings of both branches, the Patent Office and the circuit courts, may be made uniform, and the anomaly removed that now exists of one branch of the government employed in granting patents and another in destroying them. It may be said that such a court exists at this time, but we all know how far removed the Supreme Court of the United States is from the Patent Office, and how little influence it has upon its practice, besides which the existing evils have grown up under the present system, which demonstrates its incapacity to remedy them.

A strong, well-selected court of expert patent lawyers would have many advantages. It would harmonize the Patent Office and the circuit courts. It would crystallize the practice of the Patent Office, so that it would be possible for attorneys to form some conception of what that practice was and be able to advise their clients with safety with reference to their rights. The inventor could have some hope that when he had complied with his part of the government contract by disclosing his secret he would be protected in the exclusive right to use it. Such a court would lift a great burden from the shoulders of the Supreme Court, as but a small proportion of cases decided by it would be appealed to that court, and its rulings being binding upon the circuit courts, would enormously simplify the practice in those courts.

The jurisdiction of such a court should be altogether appellate, and should consist in appeals from the board of examiners-in-chief upon questions of anticipation, patentability and practice, from the examiners of interference, upon questions of priority between applicants for patent upon the same invention, and of appeals from the circuit courts of the United States upon all questions relating to patents that now go to the Supreme Court. It would be proper also to include within the jurisdiction of this court all questions now passed upon by the commissioners of patents, such as trade-marks and labels; copyrights might also be included. With such a court the duties of the commissioner of patents should be purely executive, and the jurisdiction of the Supreme Court of the District of Columbia in matters of appeal from the commissioner should be cut off. The Supreme Court of the District should bear the same relation to this court as the Circuit Court.

Passing from the question of the reorganization of the patent office to specific amendments to the law, the first question that presents itself is the question of limitation to actions.

VI.—LIMITATIONS.

It is pretty well settled by the courts that since the adoption of the Revised Statutes of 1874, there has been no limitation to the right of an owner of a patent to bring suit against an infringer for the recovery of damages for such infringement. Prior to that time, the only limitation that existed was six years after the expiration of the patent, and this seems to be the just rule. Many rules for limitation have been suggested, but it seems to me, in view of the fact which all of us have experienced, that the last few years of a patent are often the only ones during which the inventor realizes anything from his invention, that to cut him off from the recovery of damages from infringers, who may have pirated his invention during a period when he was too poor to stop them, would be unjust in the extreme.

VII.—DAMAGES.

The existing equity rules for the recovery of profits and damages for the infringement of a patent are in very satisfactory shape, but since the decision of the Supreme Court in Root *vs.* The Railroad Co., these rules do not apply to actions brought for the recovery of damages after the expiration of the patent. Such actions must be brought at law, by an action of trespass on the case, and the measure of damages under that form of action is much less liberal than the rule in equity. In an action of trespass on the case, the measure of damages is the actual loss to the plaintiff and not the gain to the defendant; while in equity, the rule allows the recovery of either the loss to the plaintiff or the gain of the infringer, whichever may be the greater, and often the difference is very great. If it is just and right that the owner of a patent should have all the benefits that may or can be derived from the use of his invention, and this is the theory of the law, and in one form of action before the expiration of his patent is allowed to recover these benefits, in the absence of a statute of limitations, why, in justice, should he be deprived of this benefit simply by the expiration of his patent? It would seem as if this evil should be remedied by legislation. It might be done by giving a plaintiff a standing in equity under a bill for an account and discovery, independent of an injunction, or if the patentee were permitted to bring an action of assumpsit for recovery of the benefit that the infringer had derived by the use of his invention, this might be almost as well; but this would require the interposition of a jury, and in complicated patent cases it is difficult to accomplish satisfactory results with a jury. It is almost impossible to make a jury understand mechanical technicalities or for the attorneys to do justice to the case upon oral testimony.

We have at this time a case in point which illustrates this rule. For seven years the owners of certain patents have been in constant litigation seeking to sustain them. We have recently succeeded in getting a decree in their favor, and a month before this decree was rendered the patents expired. The patents have been extensively infringed and cover important inventions. We have now no remedy save to sue at law by an action of trespass on the case. As a matter of fact the owners of the patents have never established a license fee for their use, but if they had, as they might have done, it would not probably have been more than $10 for each machine. Hence, this sum in our action at law would have been the limit of our possible recovery; notwithstanding the fact that the infringer by the use of each machine has saved to himself

not less than $500. Why should the rule of law in a case like this be different from that in a case where a man without my knowledge or against my will carries off my horse and uses him for his own benefit for a certain period, after which I recover him? In such a case I bring a suit and the jury estimates the benefit that the wrong doer derived from the use of my horse and awards me this amount as damages for his wrongful act. Would it be right that this wrong doer should have the power of escaping liability by answering when the jury found that he had made $100 by the use of my horse, that I could not in the same time have made but $10 with it? Would not this be putting a premium upon the wrongful act?

The question is still an open one whether in those states where the common law forms of action have been abolished, an action could be maintained at law for the infringement of a patent, the substantial result of which would be the same as the common law action of assumpsit, although the statute prescribes an action of trespass on the case as the proper action.

VIII.—REISSUES.

Since the decisions of the Supreme Court in Miller *vs.* The Bridgeport Brass Company and the line of cases that have confirmed this doctrine, it may be said that a reissue, in the sense in which that term was formerly employed, is no longer possible. The unfortunate inventor who has employed, in his ignorance, an incompetent solicitor to procure his patent, or who yields to the unnecessary limitations of the office, and whose patent issues to him covering half of his invention, or possibly contains a disclaimer disclaiming the other half, can be said to-day to have no remedy for his misfortune; and if two years have elapsed since he procured his patent, or some enterprising, manufacturer examines his patent and finding that he has not covered the second half of his invention, proceeds to make and sell that half, he is forever barred from going back and claiming it. Some change in the law should surely be made to enable an innocent and meritorious inventor to secure the full benefit of his invention, if this can be done without destroying vested property rights in individuals.

Under the present law, when a patent is surrendered in order to obtain a reissue, all accrued causes of action for past infringement upon the original patent go with it, and no action can be brought for an infringement committed prior to the date of the reissue. There does not appear to be any good reason for the existence of this rule.

At present an application for a reissue must be signed and sworn to by the inventor. This rule puts it into the power of a dishonest person to extract money from the owner of the patent by refusing to sign the reissue papers. The owner of a patent should have the power to deal with his property as he chooses, and as he is considered, when he purchased the patent, to have purchased all that could have been covered by the inventor's original application, if the patent does not do this, he should have the power to reissue his patent upon his own petition, and an oath that he is the sole owner, or if there be several, that they own the whole title.

IX.—REPEAL OF PATENTS.

The statutes of the United States contain no provision which will permit a patent supposed to have been obtained by fraud or mistake to be set aside, nor for any action by the United States against the owner of such a patent to prove the fraud and have the patent declared void. The statute should contain such a provision.

X.—EQUITY PROCEEDINGS FOR SLANDER TO PATENT.

Neither statute nor precedent in this country authorizes an equity proceeding for an injunction to restrain the continuance of slander against a machine or a patent, by one who falsely charges that the machine or the patent is an infringement of another patent owned by him, and threatens suit for such infringement, but neglects to bring such suit, and who thus continues to disturb the business of the party slandered without attempting to execute his threats or to vindicate his claim. Such an injury cannot adequately be remedied by an action at law for damages. What is wanted is an injunction from a court of equity to stop the tongue of the slanderer at once and forever.

XI.—LICENSES.

Licenses should be recorded and subject to the same rules as mortgages of land: the license first recorded should take precedence.

XII.—JOINT OWNERS.

The mutual rights of joint owners of a patent are in a very unsettled state in the present condition of the law, and it would, I think, be much safer to say that joint owners are entirely independent of one another—although there are some cases to the contrary—than to venture any statement with reference to what those mutual rights may be.

It would seem that no good reason could be advanced why joint owners of a patent should not bear the same relation to one another as joint owners of any other property. If two persons own a house jointly, but in definite proportions, and one of those persons rents the house and receives the rent for it, the other can, of course, receive his share of the rent either from the person or from the property. The absence of well-settled rules upon this subject makes it very desirable that they should be established by statute.

XIII.—U. S. PATENT LIMITED BY FOREIGN PATENT.

United States patents should not be limited to expire with the shortest lived foreign patent upon the same invention, for the simple reason that the American inventor who gives his invention as a free gift to the foreigner, gets a patent here for 17 years, while he who seeks to protect himself abroad may limit his United States patent by several years.

XIV.—ASSIGNMENT.

Assignments of patents should stand upon the same footing as conveyances of land: the assignment first recorded should take precedence.

XV.—EXPENSE OF LITIGATION.

Expense of the trial of patent cases might be lessened if the court was authorized, in impanneling a jury as provided by the act of 1875, to impannel a jury of five experts in the subject-matter of the case, pay them a suitable per diem, let them hear the testimony, and advise the court. Cochrane *vs.* Deener, 4 Otto, 784.

XVI.—INTERNATIONAL CONVENTION.

The United States by its adherence to the International Convention pledged itself to adopt legislation as soon as possible to harmonize the existing law of this country with the international law. The practical result that Americans need in relation to foreign patents is a period of say six months after they have secured an allowance of their United States patent to make their applications abroad without affecting the term of their United States patent.

I have thus rapidly touched upon the points in our patent law that need revision, without attempting to formulate specific additions to the statutes. This, I think, can only be done effectually by a commission of expert lawyers, such as is contemplated by the bill that we will introduce into Congress. In order to secure the passage of that bill, we will need the aid of every man who is interested in this subject exerted to the fullest extent; we would most earnestly urge the importance of this effort in its possible effects upon the country, and solicit your assistance in making it successful.

ELECTRIC PUMPING IN COLLIERIES.[1]

Before electricity is adopted by practical mining engineers, they must be convinced that it can compete economically with other modes of transmitting energy—modes which are well known and generally applied.

What percentage of indicated steam power applied to the generating electric machine is given off ultimately as available energy for mechanical work? How does it compare as to cost? Under what circumstances would its application be economical? If leading main questions such as these can be plainly and satisfactorily answered, practical men will not be long in arriving at a favorable opinion and acting upon it.

The application of electricity to underground pumping has enabled the writer to tabulate some particulars which he believes will go a long way toward satisfying inquirers that this is a method of transmitting energy capable of wide and economical adaptation.

Some four years ago (vol. 13, No. 5) Mr. W. B. Brain described to this institute in a short paper a small electric pumping plant at Trafalgar colliery, Forest of Dean, doing the work of about 1½ h. p. This, the writer believes, was the first attempt ever made at pumping in mines by electricity. It has continued working satisfactorily up to the present time. A similar set using about 2½ h. p. has been working in another part of the mine, some 800 yards from surface, for the past one-and-a-half years. Both are doing excellent service removing small quantities of water from remote parts of abandoned workings, which for the safe working of the colliery must be kept free from accumulations of water. It may be well to say that the majority of the collieries in the Forest of Dean have their shafts sunk on the "rise" of the taking, and the coal is won by "dipples," or engine planes, going full dip with the strata. The outcrop is riddled with old abandoned workings. These receive a great quantity of surface water, which finds its way down the slope of the strata to the deeper workings now in operation. The two electric pumps above referred to intercept some of this water on its downward course. The electrical pumping plant which the writer purposes describing in this paper has been put in to deal with the main come of water in the deep workings of the Trafalgar colliery. The pump and motor are placed a distance of about 1,650 yards from the bottom of the shafts, and the water has to be forced by this pump a vertical height of 300 feet to the pit bottom. This water had, previous to May last, been coped with by one of Hathorn Davey's water-power pumps, working in conjunction with a 7-inch double plunger Manchester Pearn pump with 10-inch steam cylinders and 14-inch stroke, the steam being obtained from the tubular boilers fixed underground.

The present pump—a double 9-inch plunger with 10-inch stroke—has been specially designed by the Lilleshall Iron Co., limited, from sketches furnished by the writer, and is fitted with spur gearing running six to one. It is driven by a leather link belt, running off a 5-feet 4-inch pulley keyed on the same shaft as the spur pinion to a 14-inch pulley on motor shaft. Thus, when the motor is running at about 650 revolutions per minute, the pump is making 25 revolutions. The motor, supplied by Elwell-Parker, limited, of Wolverhampton, is described as one of their 12-inch machines—maximum speed about 650 revolutions per minute, output about 13,000 watts. The electric current is conveyed to it by a copper cable 2,000 yards long, 19.16 wires, wrapped in compounded tape, which was supplied by the India-rubber, Gutta-percha and Telegraph Works Co., limited, Silvertown. This is enclosed in wooden boxes in the pit shaft only. It is supported upon earthenware insulators placed at intervals of about 10 yards along the side of the underground roads. The return cable is an old iron pit rope about four inches in circumference, stapled to the road posts. The generator, placed on surface near the top of the shaft, is another of Elwell-Parker's 12-inch machines. Its maximum speed is about 950, and output 17,000 watts. A belt communicates the power from a 12-inch pulley on the generator to a 5 feet 11 inch pulley attached to the crank shaft of an engine. The steam engine has a single 16-inch cylinder with 12-inch stroke, and works with about 35 lbs. steam pressure. It is an old marine engine, picked up some time since at an auction sale, and is not what one would purchase new for the work. It indicated, running empty, a loss of 5 h. p., the valves and piston both being the worse for wear. In the same engine house is another engine which supplies the power for the two small electric pumps previously referred to. The steam for both is obtained from the range of colliery boilers near. A small insulated copper wire connected to a battery of eight No. 3 Leclanché cells connects the engine house with the pump house underground, and through this is registered upon a belt in the former each stroke of the pump. It is also used as a telephone line, so that a conversation can at any time be carried on between the engine man on surface and the man in charge of the pump underground. The two smaller pumps are locked up, with no one in charge, only being visited occasionally; but with this larger one some one is thought necessary, although there is rarely anything more to be done than oil the machinery, adjust the machine brushes, and turn on the electricity. Near the engine the necessary electrical instruments—a voltmeter and an ammeter—are placed, by which the engine man knows the machines and cables are working properly. A magnetic cut-out is also placed in the main circuit, so that should the current, through any unforeseen cause increase, it automatically breaks the circuit, thus preventing the flow of electricity through the cables. The maximum speed at which the pump has been driven is 25 strokes (114 gallons) per minute. The observations taken at the time were:

Indicated h. p. of steam engine	29.49
Speed of generator	900.00
Volts at terminals of generator	320.00
Amperes ditto	43.00
Speed of motor	650.00
Volts at terminals of motor	260.00
Amperes ditto	43.00
Actual h. p. of water lifted	10.36

The first diagram exhibited is prepared from the above figures, and shows the total loss of power (19.13 h. p.) to be apportioned thus:

Loss in engine	6.49 h. p.	or 22 per cent.
Loss in generator	4.56 "	" 16 "
Loss in line	3.45 "	" 11 "
Loss in motor	3.00 "	" 10 "
Loss in pump	1.63 "	" 6 "
	19.13 h. p.	or 65 per cent.

The actual proportion of power given off by steam engine used to lift water is, therefore, 35 per cent. A second diagram shows the percentage of useful effect extracted from the power received at each stage, together with the percentage of loss, thus—horse-power indicated by steam engine, 29.49.

	H. P.		Per cent.	Useful effect. Per cent.
Received by generator	23.00	Loss in steam engine	22	78
" " cables	18.44	" " generators	20	80
" " motor	14.99	" " cables	20	80
" " pump	11.99	" " motor	20	80
" " water	10.36	" " pump	14	86

A third diagram shows the loss between the power given off at the belt of the steam engine and the actual work done, thus—horse-power given off to generator, 23.00.

	H. P.	Per cent.
Loss in generator	4.56	or 20
" cables	3.45	" 15
" motor	3.00	" 13
" pump	1.63	" 7

1. Read by Frank Brain, before the South Wales Society of Engineers, Cardiff, Nov. 24, 1887.

The proportion of power given off by belt used to lift water is, therefore, 45 per cent. As to cost, the writer has been to considerable pains to verify the following figures, knowing that with business men this is the crucial test. The following is a summary of the first cost of the plant:

Two electric machines	£310
Insulated copper lead	138
Return wire—iron rope	25
Signal wire	10
Insulators	6
Steam engine (estimate)	140
Fixing and sundries	15
	£644

The pump (£130) and pipes are not added to the above, seeing that this item of cost would of necessity be part of any set of plant, and it would therefore be an item of cost common to all systems.

Detailed cost of pumping 114 gallons per minute with above machinery, through 1,300 yards 7-inch pipes—main rising 300 feet—one week's pumping, 22 hours per day:

	£	s.	d.
Engineers (half time)	1	8	0
Man underground (full time)	2	9	0
Small coal consumed, say 36 tons at 1s.	1	16	0
Oil, waste and sundries	0	7	0
Say 15 per cent	1	17	0
	£7	17	0

Cost per horse-power on water raised, .02 of a penny; cost per 1,000 gallons of water raised, 1.80 pence.

The come of water in the deep workings of the colliery has been much below the average during the past dry autumn. The pump has therefore been usually worked at about 64 gallons per minute. The results, of course, not being so good, are as follows: Proportion of power generated used to lift water, 32 per cent.; cost per horse-power in water raised, 0.3 of a penny; cost per 1,000 gallons of water raised, 3 pence.

When opportunity offers, and the hold of water is pumped out, this plant is utilized to assist in maintaining the ventilation. Some 1,200 yards underground a small fan, passing some 10,000 cubic feet of air per minute, is placed in a return air way. A branch connection is made from the main cable to a dynamo which drives the fan by belt connection. The cost of maintaining the present plant, compared with that it has supplanted, shows an economy of about £470 per annum. This the writer does not, however, rely upon as a fair comparison of cost, seeing that the former plant had to be worked under most disadvantageous circumstances.

The whole of this plant was supplied by the various makers to specification, and was put in by the colliery mechanics without any outside assistance. It commenced working without a single hitch, and has worked continuously since the end of May last with but one accident. This, strictly speaking, cannot be spoken of as an accident. A couple of weeks ago we found much more current was being taken to do the ordinary work than usual, and on examination traced the cause to the cable in the pit shaft.

Here, as already explained, the cables which are not highly insulated are carried in wooden troughs. The late continuous heavy rains had very much increased the feeders of water in the shaft, and this water, finding its way into the boxes saturated the cable, causing a great escape of electricity. A lead-covered cable was substituted for the ordinary one, and the difficulty was thus completely overcome.

The cable was a matter of some anxiety when the plant was being provided, as the writer feared that falls which cannot be prevented on underground roads would be constantly damaging it and causing delays.

In practice this has never been yet found to occur. With the one line indestructible (as the iron pit rope practically is), the other, should it be damaged, can quickly and easily be repaired or replaced with new, so that this, one of the most formidable of the anticipated difficulties, has proved quite illusory. The plan which has been adopted of supporting the cable upon earthenware insulators has proved a good one, more perfect insulation, a very important factor, being obtained. The repairs necessary to the side timber of the roads along which the cables are suspended is also facilitated.

The commutators are the principal electrical wearing parts, and with care these will run a considerable time. In this instance, after five months' work, the wear shown is only about one-sixteenth of an inch, although there is an inch thickness of copper to be worn away before it is necessary to have a new one. With a spare armature kept in hand, which costs about one-third the price of a machine, no accident can happen which the colliery mechanics cannot repair, and that with little delay, everything being simple in construction and easily to be got at.

It is an advantage which colliery managers will appreciate to concentrate work and have it under personal supervision. Given sufficient engine power, any reasonable number of generators can be driven in one engine house on surface, delivering power to distant places underground at various points of the compass. These dynamos would require but one man to attend to them, and the work done could with ease be supervised. The steam, too, can be generated at least possible cost under such circumstances, and with the work divided between two or three engines, a breakdown with either, should it occur, need not cause any delay. It is especially noticeable that this plant can be put down economically and with great despatch. With pipes carrying steam, compressed air, or water, it is often necessary to place them in ditches specially made at considerable expense along the sides of the underground roads, so as to protect them from injury and keep them out of the way.

The outlay in pipes is also great, more especially when the route is devious, and if the roads are at all given to "puck," these are constantly being broken.

With electric cables none of these difficulties occur. No matter how intricate the route may be, a thousand or two thousand yards can be put to work in as many hours as it would require weeks to put in pipes. Given a pump with the necessary suction and delivery pipes fixed a mile underground, with steam-power available on surface, and it would be practicable to have that pump in work in less than a week, an impossibility with any other method.

A few brief extracts from papers already published, comparing the cost of electricity with the power derived from steam, compressed air or hydraulics, may be interesting.

The following is given by Professor Schulz ("Proc. Inst. Civil Engineers," vol. 78, p. 67, and "Transac. N. of Eng. Institute of Engineers," vol. 34, p. 5). Total cost of underground haulage by locomotive:

	Per ton in pence.
Steam engine	1.0
Electric engine	1.54
Compressed air engine	2.06

Total cost of various systems of underground haulage:

	Per ton in pence.
Endless chain	0.98
Rope and counter rope	1.26
Electric locomotive	1.54
Rope and tail rope	1.89
Endless rope	2.83

A comparison between electric transmission and mechanical methods was published in Berlin, in 1883, by A. Beringer, and awarded a prize by the Electrotechnical Society there.

A *resumé* of it appears in the "Revue Universelle des Mines" (ser 2 tome 15, p. 522). The following brief extract may be of interest:

Comparison of cost on 10 effective horse-power hours transmitted 1,093 yards :

By cables	1.77d.	per effective horse-power per hour.
" electricity	2.21d.	" " " "
" hydraulics	2.90d.	" " " "
" compressed air	2.98d.	" " " "

Comparison of cost on 50 effective horse-power hours transmitted same distance :

By cables	1.85d.	per effective horse-power per hour.
" hydraulics	1.87d.	" " " "
" electricity	2.07d.	" " " "
" compressed air	2.27d.	" " " "

Comparison of cost on 10 effective horse-power hours transmitted 5,645 yards :

By electricity	2.64d.	per effective horse-power per hour.
" compressed air	4.66d.	" " " "
" cables	4.69d.	" " " "
" hydraulics	5.29d.	" " " "

Comparison of cost on 50 effective horse-power per hour transmitted 5,465 yards :

By electricity	2.37d.	per effective horse-power per hour.
" cables	2.65d.	" " " "
" compressed air	2.99d.	" " " "
" hydraulics	3.02d.	" " " "

Steam was the prime motor used in each instance. From the above figures it is to be inferred that for distances of about 1,000 yards cable transmission costs least, but that in longer distances electricity takes the lead and maintains it against all other systems. The cost per effective horse-power per hour of the electrical pumping plant herein described is found by the figures as to cost, already given, to be 1.18d. It is obvious that a future is before electricity in the transmission of power. For coal cutting, it affords a ready means of distributing power ; for hauling engines, which can either be stationary or run to various parts of the colliery on prepared tracks—as well as in pumping—this new motive power must take a place, and that no despicable one, in the future of colliery work.

APPLICATION OF ELECTRICITY TO LOCKS.

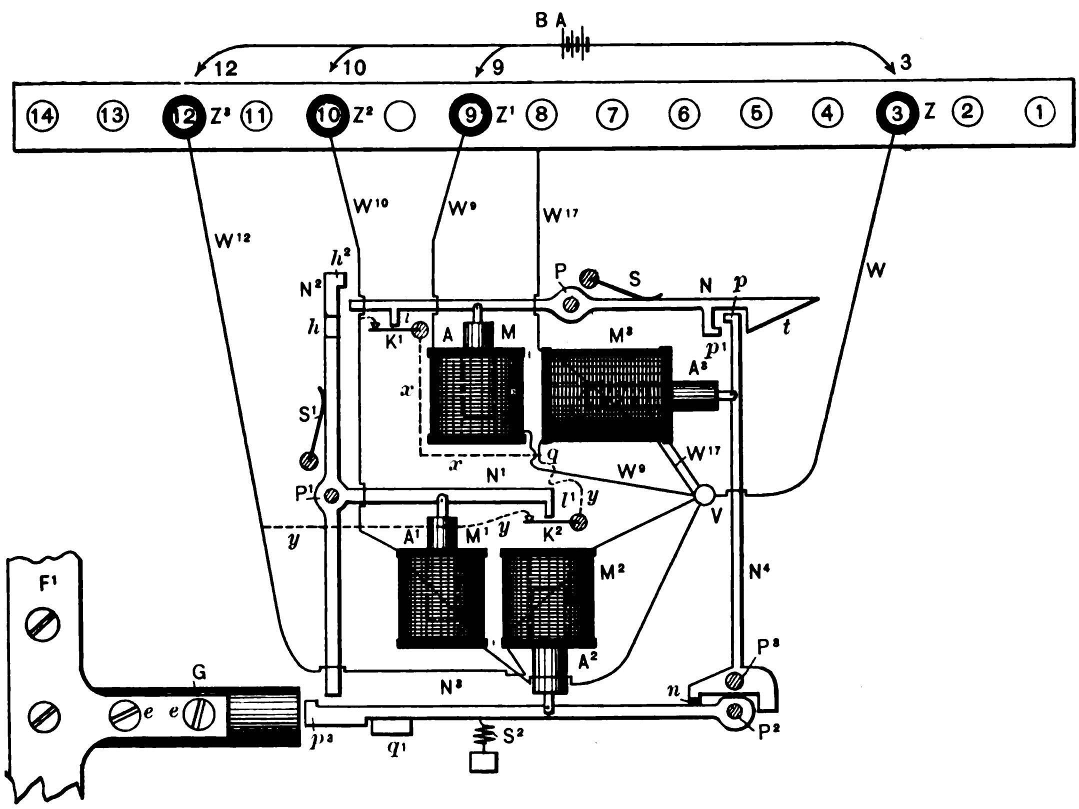
We give below a description of one of a series of electrical combination locks recently patented to Mr. C. J. Kintner, late Principal Examiner in the U. S. Patent Office.

The inventions covered by Mr. Kintner's patents are novel and very interesting, and to say the least, they exhibit a new extension of electric art in usefulness to the world by affording security to valuables and foiling the attempts of burglars, adding one more to the rapidly multiplying means of safety and convenience in the world of business.

It is claimed for these locks that they are decidedly more simple in their construction and mode of operation, and, therefore cheaper and more secure than well-known forms of mechanical combination locks.

The sketch shows the locking parts in the interior of a safe, the battery, or preferably a magneto generator, being located on the outside.

A series of insulated wires, say 50 in number (in the



sketch shown as 14), lead from the exterior of the safe to a switch-board within, all of these wires being electrically connected to such switch-board, as shown, save in this instance, numbers 3, 9, 10 and 12, which are insulated therefrom by washers and have continuing conductors W, W^9, W^{10}, W^{12}, and W^{17}, all leading to a common binding post V, the wires, W^9, W^{10}, and W^{12}, being connected respectively through the electro magnets or solenoids M, M', M^2, while the separate conductor W^{17} runs from the switch-board to and through a safety magnet M^3 to the same binding post V. The wire W answers as a return wire for all four of the wires W^9, W^{10}, W^{12}, and W^{17}.

X and Y are shunts normally closed about the magnets M' and M^2 by the springs K' and K^2 lying in the path of the lugs l and l' on the armature levers N and N'; S S' S^2 are retractile springs for holding all of the levers in their locked positions.

N^4 is a safety lever pivoted at P^3 and having a soft rubber spring, n, on its short arm bearing against the locking lever N^3, so that when said lever is drawn up by the action of the solenoid M^3 it will tend to hold locking lever N^3 in

its locked position and at the same time cause its hooked end, p, to engage the hook p' on lever N.

The shunts X and Y unite at q and pass thence in a direction about the core of solenoid M^3 the reverse to that of the main coil joined to W^{17}, so that if the circuit is closed at 10 or 12 through any other number outside the safe this safety magnet will be actuated and permit the operation of the lock. The outer ends of the insulated wires lie beneath two horizontal metal rods (not shown), one of which is attached to the plus pole of the battery and the other to its minus pole. On one of these bars is a sliding contact maker and on the other are three similar to the first, all of which are adapted to connect the contacts lying under them directly to the battery as they are slid along across the outer face of the safe door.

The operation is as follows: The combination numbers are in this instance, 3, 9, 10 and 12, being chosen from a series of 14 numbers; while the other 10 numbers are connected to the safety circuit by direct contact with the switch-board and wire W^{17}.

To open the lock, place the contact maker of, say, the lower horizontal rod attached to the face of the safe upon the exterior contact point 3; next place any one of the three contact makers of the upper horizontal rod on point 9. The battery circuit will then be closed from the copper or plus pole as shown by the arrow at 9, to and through insulated wire number 9 to the inside of the safe, and thence by wire, W^9, magnet or solenoid M to post V, by wire, W, to point 3, and finally to the exterior of the safe and minus pole of the battery, as shown by the arrow.

This energizes solenoid M, and causes its core to turn the lever M about its pivot P against the action of spring S, and to bring the lug l into mechanical contact with spring K′, thus breaking the shunt X to the second magnet, M′, of the combination, and at the same time drawing the hook p' out of the path of the hook p on the safety lever N^4.

Now cause the second contact maker of the upper horizontal contact rod to be placed upon the point 10, the second number of the combination, and the battery will be closed in multiple arc by the path already described, and a second path from point 10 by wire 10 through the door to inner point 10, and wire W^{16} to and through magnet or solenoid M′, thence to common point V and out by wire W as before. Magnet or solenoid M′ is energized, causing lever N′ N^2 to tilt about its pivot p', so as to carry the lower end to the left out of the path of the locking lever N^3, and at the same time cause the upper end N^2 to mechanically lock the lever N which now extends into the opening h.

This same action breaks the shunt Y of the last locking magnet M^2 at the spring l^2 by means of lug l^1 on lever N′.

The first circuit may now be broken if desired. The last circuit is now closed by placing the last contact maker on the upper horizontal contact rod in contact with the point 12 beneath it, when the circuit is again closed through the additional multiple arc branch W^{12}, magnet M^2 and common return wire W, thus causing the last or locking lever N^3 to be drawn up against the action of spring S^2, and out of the path of the lug G on the bolt frame F′.

The bolts may now be drawn by turning the bolt handle (not shown) in the usual manner, and this lug G will be forced to the right under the raised end of the locking lever N^3. The circuit may now be broken at point 3 and the combination contact maker slid along to any desired position on the horizontal rods which support them. These rods are not shown in the sketch. On returning the bolts into locking position, the locking lever N^3 and the levers N^2 N, all fall into locking position under stress of their springs S S′ S^2.

If the circuits be closed in any other order than that indicated, the safety magnet M^3, will be actuated and cause its lever N^4 to firmly hold the last locking lever in position, and at the same time lock the lever N against action.

The arrangement is such that each armature lever locks its companion, and they all in turn lock the bolts.

In the simplest form of lock made by Mr. Kintner, the shunts are omitted, thus avoiding liability of derangement of contacts on the inside of the safe. He is building a safe with such a lock, and will place it on exhibition within a month.

It will be seen that this lock simplifies the operation of entering safes very materially, and it is found that four seconds at the utmost will suffice to draw the bolts.

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

THE electro-deposition of iron, although it has met with some few applications—but more especially in the so-called "steel-facing" of engraved copper plates and printers' type—has not yet received so much attention in this country as it deserves. Indeed, iron-plating—which is a better term than *ironing*, which would smack rather of the laundry—and iron electrotyping may be said to be as yet but in their infancy, so far as development is concerned. There can be no doubt that if iron electrotypes could be as freely obtained as we produce those of copper, a very important field of enterprise would be opened up for those who follow the art of electro-deposition. Before this desirable object can be attained the study of various solutions of iron salts, with and without the addition of other substances, must receive further consideration. With a view to aid those who are interested in the electro-deposition of iron generally, I purpose giving the results of a series of experiments which I have made from time to time in the deposition of iron, from which it will be seen that while there are many iron salts from which the metal may be deposited readily and of good quality, other salts are totally unfit and valueless for the purpose. When desirous of taking up any new branch of electro-deposition, it is advantageous to the student, not only to know the nature and behavior of those materials which are most suitable for his purpose in a practical sense, but he should also have some knowledge of the short-comings of other salts of the same metal in case at any time he might be tempted to experiment in the same direction himself.

In depositing iron from its various solutions many difficulties have presented themselves which ingenuity has to some extent overcome. The rapid oxidation of the iron salt of the surface of the electrolyte, and the blackening of the deposit at the corners and edges of the plate have, amongst other sources of annoyance, been the most troublesome causes of failure. Again, with some solutions it has been found that the anode did not dissolve with sufficient readiness to keep the bath up to its normal strength. These faults have, however, been to some extent overcome, and so far as light deposits are concerned—such as in the facing of engraved copper plates—the deposition of iron presents but little difficulty. The production of iron electrotypes, however, has yet to receive further development before the process becomes a practical art of general application.

In describing the various solutions of iron which I have electrolyzed, with a view to determine what character of deposit they were capable of yielding, it may be well that I should also refer, in passing, to those solutions which have hitherto been employed or recommended for the deposition of this metal. In making up baths from any of the well-known solutions, I would recommend the operator—regardless of prescribed formulæ—always to make his solution a trifle too weak rather than adopt the other extreme, since weaker solutions will often give far better results than stronger ones, and the gradual strengthening of the bath can readily be resorted to if occasion requires it. Too strong a solution of any iron salt is pretty sure to give an indifferent deposit and cause disappointment, whereas with a weaker solution—if it be a good one in other respects—the deposition is merely slow, a fault easily remedied by the *gradual* addition of more iron salt. The alterations of the strength of the bath should never be made, however, until the operator has satisfied himself that the current is adequate. When practical, the solution (proto-sulphate, for example) should be put into such a condition that it will work well with a surface of anode about equal to that of the cathode, when working at the ordinary temperature. With some solutions, however, this would not be practical, as in cases where other salts besides those of iron are used for preparing the bath, which have little or no solvent action upon the iron anode.

Proto-Sulphate of Iron.—Various proportions of this salt to the gallon of water have been employed in making up baths for depositing iron, but I found the following give exceedingly good results with a somewhat weak current: About half an ounce of good sulphate of iron was dissolved in a pint of cold water. One small Daniell cell was first tried, with electrodes of about equal surface, but the deposit was of rather dark color. A few drops of sulphuric acid were then dropped into the bath, and an extra cell connected, when a considerable improvement in the color was

manifest; a third cell was now added—the whole being in series—when the deposit became exceedingly white and bright, which character it maintained. At the end of about two hours the plate (sheet copper) was withdrawn, when its brilliant appearance resembled that of copper which has been dipped in mercury. There was considerable evolution of hydrogen. On examining the anode (a plate of wrought iron), it was found to have been very equally and very freely acted upon, and presented a very clean surface.

Proto-Chloride of Iron.—A moderately strong solution of this salt did not yield a good deposit; neither was the color of the film improved by diluting the solution. In all conditions of the liquid the deposited metal had a tendency to blacken after a short immersion of the negative plate. The best results were obtained with two Daniell cells.

Ammonio-Sulphate of Iron.—A solution of this salt, used with a rather weak current, is undoubtedly one of the best for the deposition of iron. The solution is greatly improved, however, by the addition of a moderate quantity of acetic acid. I found the following proportions yield a very white deposit of iron with two small Daniell cells:—Ammonio-sulphate of iron 1¼ oz., water one pint. The deposit, though not so bright as that from the proto-sulphate before referred to, was very white and uniform in character; there was no blackening of the film at the corners of the plate, and deposition took place very freely.

Tartrate of Iron.—A solution of this salt was prepared by dissolving recently precipitated hydrated sesquioxide of iron in a strong and hot solution of crystallized tartaric acid. With two Daniell cells little or no deposit took place. With five cells the film was white at the lower part of the plate, but the remaining surface was of a dark color. The solution is a bad conductor, and not suitable for any practical purpose.

Phosphate of Iron.—Recently precipitated carbonate of iron was dissolved in a strong and hot solution of phosphoric acid. Five cells were used, when a white deposit of iron was obtained upon a copper plate almost immediately. The coating soon became dull, however; and after about half an hour or so the liquid became decomposed, a white precipitate being formed, which settled upon both electrodes and floated about in the liquid. The white salt thus formed was doubtless the proto-phosphate of iron.

Salicylate of Iron.—A solution of this salt was prepared by dissolving recently precipitated carbonate of iron in a hot solution of salicylic acid, when a deep red liquid resulted, which yielded a tolerably prompt deposit of iron of a darkish color, but fairly adherent, upon a copper surface. Five cells were necessary to obtain a successful deposit.

Potassio-Tartrate of Iron.—A solution of this salt yielded a tardy but bright deposit of iron, with five Daniell cells. The solution was not a good conductor.

Sulphate of Iron (*Klein's method*).—A solution of sulphate of iron is precipitated by means of carbonate of ammonia; the precipitate is then well washed and afterwards dissolved in sulphuric acid, care being taken to avoid excess of acid. The solution is used in as concentrated a state as possible. It is stated that good reguline metal may be obtained from this solution by means of a current from four weak Meidinger cells, with an iron anode and cathode of copper. In working this solution it is important to prevent it from becoming acid, for which purpose an anode eight times larger than the cathode, or receiving plate, must be used, and a plate of copper or platinum attached to it, so that the two form a voltaic couple in the liquid, and thus cause the iron to dissolve when the current is not passing.

Perchloride of Iron.—A solution of this salt does not yield a deposit of iron. In electrolyzing a solution of the perchloride, very carefully prepared, a white deposit was at first obtained, which, upon examination, gave a trace of iron, but a greater portion of the film was insoluble either in sulphuric or hydrochloric acid. The deposit was probably due to some metallic impurity of the peroxide (rouge) employed, but this I have not yet determined.

Persulphate of Iron.—This salt also yields no deposit of iron by electrolysis. A copper plate became coated with a dark-colored film, insoluble in either sulphuric or hydrochloric acid, and was probable due, as in the former case, to some metallic impurity of the hydrated sesquioxide of iron employed—though how such a foreign metal could find its way into the precipitated hydrate is a mystery, since it was prepared from an apparently pure sample of jewelers' rouge dissolved in hydrochloric acid and precipitated by ammonia.—*The Electrician* (London).

(*To be continued.*)

THE GENERAL THEORY OF DYNAMO MACHINES.[1]

BY EDWARD HOPKINSON, D.SC.

USING the term "dynamo" in the widest possible sense, including under it all machines for the conversion of mechanical forms of energy into electro-magnetic, and electro-magnetic into mechanical, there are certain characteristics common and essential to all types of such machines, whether they be known as magneto machines, alternate current machines, or continuous current machines, either compound, shunt, or series wound, and of the drum, ring, or disc type. It is therefore possible, up to a certain point, to construct a theory of dynamo machines which is perfectly general in its application. The object of the present paper is to trace briefly the outlines of such a theory, and to indicate how the consideration of specific types of machines can be developed therefrom, and in what direction research is required to elucidate some points still obscure. A dynamo consists essentially of two closed circuits or "tubes," in both of which there is a displacement of the nature of a flux dependent upon the relative motion of the two circuits. We may call one of these the "magnetic circuit" and the other the "electric circuit." Either or both of these may be in motion; but as we are concerned only with the relative motion of the two, we may for convenience (as, in fact, is usually the case) regard the magnetic circuit as fixed, or displaced only by the reaction of the electric circuit upon it, and consider the latter only as moving under external forces, whether electric or mechanical. The flux along the magnetic circuit is called the "magnetic induction," which is a vector or directed quantity, requiring for its definition reference to co-ordinate axes. It is subject to the fundamental condition known as the "solenoidal condition," or "equation of continuity," which may be expressed in words "that the flux across all sections of the tube is the same," or otherwise "the induction through any surface bounded by a closed curve depends only on the form and position of the closed curve, and not on that of the surface itself." The flux along the second circuit is called the "electric current," and is also a vector quantity, subject to the solenoidal condition. Neither circuit is necessarily bound by the limits of the machine, and both may be, and generally are, subdivided. Both these fluxes are produced by corresponding forces, called respectively "magnetic force" and "electromotive force," which likewise are vector quantities, but are defined by reference to a line instead of by an area, as is the case with the fluxes. (Maxwell. "Treatise on Electricity and Magnetism," vol. i., page 10.) The solenoidal condition for magnetic induction is a direct deduction from Coulomb's original experiment, verified by all subsequent observations in magnetism. We now require to know the relation between each force and its corresponding flux. Let us first inquire into the relation between the magnetic induction (B) and the magnetic force (H). Such a relation may be expressed by the general equation

$$B = f^{-1} (H).$$

The form of the function depends upon the medium in which the tube is drawn, and also upon the physical conditions of the medium. For air and all other gases, and generally for all substances classed as "non-magnetic," it is a linear function possessing one co-efficient or constant only. For such substances the equation may be written

$$B = \mu H.$$

Since the numerical definition of H is at our disposal, we may so define H that μ is unity for all the substances above referred to, and write

$$B = H.$$

For iron, and generally for all magnetic substances, H is not a linear function of B, and its expression will involve several constants depending upon the medium, and such physical conditions as temperature and strain, and its previous history. The determination of the form of the function for iron in particular has been the subject of a great number of experiments, but no general expression has yet been discovered, and it has usually been found most convenient to record the experimental results in the form of a curve referred to rectangular axes, in which the ordinates represent magnetic induction and the abscissæ magnetic force. Such curves have been fully investigated for iron of various composition, and under varying physical conditions, among others particularly by G. Wiedemann (Die Lehre vom Galvanismus, vol. ii., page 340 and sequor), Rowland (*Phil. Mag.*, August, 1873), Carl Barus and Vincent Strouhal (Bulletin of the United States Geological Survey, No. 14, 1885), J. Hopkinson (Philos. Trans. of R. S., part ii., 1885), J. A. Ewing (Philos. Trans. R. S., part ii., 1885, and part ii., 1886, and Proc. of R. S., vol. xlii., page 200, 1887). By reference to these memoirs it is now possible to construct the curve with fair accuracy for iron of any known composition. For convenience we may express the curve by the equation

$$B = \mu H.$$

μ is then the tangent of the angle which the tangent to the curve makes with the axis of x. It has received various names; by Sir William Thomson, "permeability" (Reprint of Papers on Electricity and Magnetism, vol. ii., page 54); by Maxwell, "coefficient of magnetic induction" (Treatise on Electricity and Magnetism, vol. ii., page 54); and again, "magnetic inductive capacity" (vol. ii., page 243).

Secondly, we require to know the relation between the E. M. F. and current. This is well known to be expressed by a linear rela-

1. Read before the British Association for the Advancement of Science (Section A.—Mathematical and Physical Science), Manchester, September 6, 1887.

tion, known as Ohm's law, involving one constant coefficient only, universally designated the "resistance."

$$E = R\,C.$$

E being the E. M. F., and C the current. As far as all experimental evidence goes, R and the reciprocal of μ possess the same two characteristics, viz., that for any given substances in any defined physical condition they are proportional to the length of tube considered, and inversely proportional to its cross-section; μ may therefore without impropriety be called the reciprocal of the "magnetic resistance," but as expressing this analogy only. It must be distinctly remembered that for magnetic substances there is no such relation as Ohm's law.

Having now defined the relation between the fluxes and their corresponding forces, it remains to consider the relation between the fluxes themselves, dependent upon the relative motion of their circuits. This may be expressed in various ways, all of which are the expressions of Faraday's well-known law: (1) The line integral of the E. M. F. round the electric circuit is the rate of decrease of the surface integral of magnetic induction through any area bounded by the circuit; or (2) the time integral of the total E. M. F. round the electric circuit together with the surface integral of the induction through the circuit is a constant quantity. Again, since the surface integral of any vector over any surface which satisfies the solenoidal condition can be expressed by a line integral round any closed curve bounding the surface, a new vector may be introduced called the "vector potential" of magnetic induction, which is such that its line integral round any circuit is equal to the surface integral of induction over any surface bounded by the circuit. Also the time integral of the E. M. F. in any circuit is the electro-magnetic momentum. Hence Faraday's law may be expressed. (3) The electro-magnetic momentum of a circuit is the line integral of the vector potential round the circuit (Maxwell, vol. ii., pp. 28 and 234).

Excluding for the moment the consideration of magneto machines with permanent magnets, and of machines in which iron plays no part whatever, we may more particularly consider that class of dynamos in which the magnetic field is produced by the use of iron excited by a current; and we then require to know the relation between the current and the induction in the magnetic field produced by the current. Faraday showed that the magnetic field in the neighborhood of an electric current is the same as that of a magnetic shell bounded by the circuit of the current, and has therefore a similar magnetic potential. This is expressed by saying (4) that the line integral of magnetic force round any closed curve is zero, provided the closed curve does not surround the electric current, and if the current passes through the closed curve, then the line integral is proportional to the number of times it passes through, and is equal to $4\,\pi\,n\,c$, where c is the current and n the number of times it passes through the closed curve.

If we take the magnetic units as fundamental, the propositions (1) and (4) define the units of E. M. F. and current, On the other hand, if we start with the arbitrary units of E. M. F. and current, based on quite other considerations, the propositions define the units of magnetic induction and magnetic force in terms of these.

We have now the materials for a complete investigation of a dynamo of any given configuration and constructed of iron, whose magnetic qualities are known. It is required to determine the E. M. F. and current in the electric circuit, as its configuration relative to the magnetic circuit is changed by the application of external forces, and as the magnetic forces in the magnetic circuit are changed either by external electro-magnetic forces or electro-magnetic forces derived from the current circulating in the electric circuit. The magnetic circuit consists in general of four parts: (1) The magnet limb, which is surrounded by coils of wire, through which the exciting current is passed, which may be derived either from external sources or may be part of the electric circuit of the machine. (2) The field pieces, or the extended polar extensions of the magnet limb, embracing the armature. (3) The air space, being the necessary interval between the iron of the pole-pieces and the iron of the armature, or in cases where the armature contains no iron, the interval between the opposed pole-pieces. This interval may be an entirely free air space or partially occupied with other non-magnetic matter, according to the particular type of machine. (4) The armature, or that part of the machine carrying that portion of the electric circuit which is subject to displacement under external forces. There may be other subsidiary portions of the machine, *e. g.*, the magnet limb may be divided into one or more portions connected by yokes, but as these may be treated in exactly the same way as the pole-pieces, they do not require special consideration. Again, the magnet limb may be divided so as to form several magnetic circuits; each of which may be considered independently. In alternate current such sub-division is universal, and is not infrequent in continuous current machines.

The magnetic circuit is thus subject to magnetic forces due to the current in the armature and the current round the magnet limb. We must therefore, in the general case, take these as two independent variables, which we may denote by C and c. Now, it may be assumed with sufficient accuracy that in the magnet limb the boundaries of the tube of magnetic induction are coincident with the boundaries of the iron, and the cross-section of the tube the same as the cross-section of the iron. Outside the limb a portion of the lines of force will complete a magnetic circuit through external space, and will not enter the pole-pieces. The extent of this leakage or induction, from which no useful effect is obtained, depends upon the configuration of the machine and the degree of saturation of the iron, and could be calculated therefrom; but as it can be experimentally determined for any machine with great ease, it is unnecessary to consider it further, and we may regard the total induction in the magnet limb as greater than the induction in the pole-pieces in a constant ratio, which we will denote by ν_1. It is usual to construct the pole-pieces of large section compared with the magnet limb, and hence the section of the pole-pieces may again be taken as the section of the tube of induction; but as the lines of force leave the pole-pieces to cross the air space, we cannot ascribe any boundary to the tube, but in every machine a portion only can pass through the armature, and part must pass from one pole-piece to the other by lines external to the armature. Moreover, the relation between the two parts will not be a constant one, unless the magnetic forces in the armature are constant, which can never be the case. It is therefore necessary to consider the tube of induction, which crosses the air space and enters the armature, as a variable portion of the whole tube, the variation depending upon the magnetic forces in the armature. We may denote the ratio of the induction through the pole-pieces to the induction through the armature by ν_2. Knowing now the components of the magnet circuit we can determine the magnetic forces in the several parts, and hence obtain the induction in the tube. Let A_1 be the cross section of the magnet limb, l_1 its length; A_2 the cross-section of the pole-pieces, l_2 the mean length of the tube therein; A_3 the cross-section of the air space, comprising all the space through which the lines entering the armature pass, l_3 its length; A_4 the cross-section of the iron of the armature (if it contains iron), and l_4 the mean length of the tube of force therein. Then the line integral of magnetic force taken round the circuit is:—

$$\frac{1}{\mu_1} l_1 \frac{\nu_1 \nu_2 I}{A_1} + \frac{1}{\mu_2} l_2 \frac{\nu_2}{A_2} - \left(\frac{1\ l_3}{\mu_3 A_3} + \frac{1\ l_4}{\mu_4 A_4} \right) I$$

the μ's being the coefficients of magnetic induction for the several portions of the circuit. For air the coefficient is unity, hence $\mu_3 - 1$. I is the total induction in the armature, which is assumed to be uniformly distributed over the tube. The integration has extended along the tube only which passes through the armature, and hence the forces along the portions of the whole tube which pass outside the machine do not appear. Now, the magnetic circuit is cut by the current in the magnet coils and the current in the armature. Let n_1 be the number of times it is cut by the former, n_2 by the latter. Then

$$\frac{1}{\mu_1} l_1 \frac{\nu_1 \nu_2 I}{A_1} + \frac{1}{\mu_2} l_2 \frac{\nu_2 I}{A_2} + \left(\frac{l_3}{A_3} + \frac{1}{\mu_4} \frac{l_4}{A_4} \right) I - 4\,\pi\,(n_1\,c + n_2\,C)$$

It must be noted that the direction in which the circuit is cut by c and C is in both cases taken to be positive. Referring to three rectangular axes and measuring the induction along the axis of z, the current round the magnets along the axis of x, and that in the armature along the axis of y, the above equation may be written

$$l_1 f_1 \left(\frac{\nu_1 \nu_2 z}{A_1} \right) + l_2 f_2 \left(\frac{\nu_2 z}{A_2} \right) + l_3\ \frac{z}{A_3} + l_4 f_4 \left(\frac{z}{A_4} \right) - 4\pi(n_1 x + n_2 y$$

This represents a surface, the ordinate at any point of which is the induction through the armature. Such a surface was first described by Doctor John Hopkinson (Lecture before the Inst. of C. E., April, 1883), and is called the "characteristic surface." It must be remembered ν_1 is a constant coefficient, or may be taken as such with sufficient accuracy, but ν_2 is not constant. It is unnecessary to consider further its general form, as it may better be determined in connection with the particular type of machine under consideration. $f_1\,f_2\,f_4$ would be the same functions if the quality of the iron were the same in the several portions of the machine.

Having obtained a general expression for the induction in the armature, the electromotive force in the electric circuit, when displaced, can be deduced by Faraday's law.

Consider now the application to alternate current machines. Such machines are usually multipolar. In machines of the disc type the number of poles is even, and the armature is divided into sections corresponding to the number of poles, and revolves uniformly between them. The tube through any one pair of opposed poles and back through another need only be considered, and the total effect of the machine obtained therefrom by summation. Suppose the iron of both magnets and armature so arranged that no currents are induced therein. There is then only one electric circuit to deal with. The whole current in one

section of the armature cuts the magnetic tube passing through the section as many times as there are convolutions. Let m be the number of convolutions. The current, x, round the magnets is usually derived from independent sources, and maintained constant. For each such constant value the characteristic surface becomes a curve giving the relation between the induction through the armature and the current in it. The areas A_1, A_2 and A_4, and the lengths, l_1, l_2, l_3 and l_4, are constant, but the area, A_3, is a periodic function of the time, and can be expressed by a series of cosines, the coefficients of the series being determined by Fourier's theorem from the dimensions of the machine. The general consideration of the form of ν_2 has been worked out by Doctor J. Hopkinson (Proc. R. S., 1887), and need not be referred to further. The induction is a function of the time; but as an example, consider its value at that epoch when the cores of the armature are exactly opposed to the pole-pieces.

$$\frac{l_1 \nu_1 \nu_2 \mathrm{I}}{\mu_1 A_1} + \frac{l_2 \nu_2 \mathrm{I}}{\mu_2 A_2} + \left(\frac{l_3}{A_3} + \frac{l_4}{\mu_4 A_4}\right) \mathrm{I} - 4\pi n_1 c - 4\pi m \mathrm{C}$$

Since the coefficients are all determinate by measurement or experiment, I is obtained in terms of c and C. Assume that, instead of continuous rotation of the armature, the action of the machine is such that each core of the armature is moved periodically in an infinitely short time from between one pair of poles to the next. Let T be the periodic time, E the electromotive force, then

$$\mathrm{E} = m \frac{2\pi}{\mathrm{T}} \mathrm{I}.$$

Hence E is determined in terms of c and C. E is here the maximum E. M. F. The E. M. F., as measured by a Cardew voltmeter or equivalent instrument, will be $\frac{1}{\sqrt{2}}$ of the maximum.

If the equation of the characteristic be differentiated with regard to the time, we shall obtain an equation of the form

$$\mathrm{A}\, \dot{y} + \mathrm{B}\, y = \text{periodic function of } t,$$

when B is constant and A is a periodic function of t, but usually assumed to be constant, and called the "self-induction" of the machine. In the case of an alternate current machine there are usually other magnetic forces acting upon the electric circuit external to the generating machine. For instance, the electric circuit may contain a transformer, or a second machine inserted as a motor, or an arc lamp in which there is a constant E. M. F. changing sign with the current. It is not then sufficient to consider the magnetic tube within the machine only, but the effect of all other tubes which are cut by the circuit must be included, and the characteristic surface of the whole system obtained by summation. These cases have been worked out, taking A as by Doctor J. Hopkinson. (*Journal of Telegraph Engineers*, 1884.)

Now consider the application to continuous current machines. With the exception of certain types of dynamos, like that of Professor Forbes or the cylinder dynamo of Doctor Werner Siemens, in general no current continuous in direction can be obtained by continuous rotation of any part of the electric circuit, unless arrangement is made for reversing the current at a certain stage of each revolution. If the rotating part contained one section only, the current, though continuous in direction, would oscillate from zero to its maximum. To avoid this the electric circuit is divided into a number of sections, arranged symmetrically on the armature, the current in one or two of which only is reversed at a time. If the number of sections be even and equal to $2\,m$, one-half will be in series, and one-half the total current will pass through each half, except at the instant of commutation. At such time two sections are short circuited, and form complete circuits inwhich the current will be determined by the induction through them at the time; and the number of sections in series will be $m - 1$. If the number of sections be odd and equal to $2\,m + 1$, one section only will be commuted at a time, and at that instant there will be m sections in series. At other times there will be $m + 1$ sections in series on one side and m on the other, and consequently there will be a superposed current flowing through the armature only, due to the inequality in the number of sections in series in the two halves. In one revolution of the armature the tube of induction through it will be cut four times by each section, and if the plane of commutation is symmetrical with regard to the tube of induction, the current in one-half the sections will cut it in the opposite direction to that in the other half. In this case, $n_2 = o$. But any displacement of the plane of commutation from the symmetrical position will cause the current in a greater number of sections to cut the tube in one direction more than in the other. Let λ be the angular advance of the plane of commutation, and m the number of sections in the armature; then $n_2 = \frac{\lambda m}{\pi}$. The value of λ may be fixed for any given machine, or varied at pleasure, or may be determined to avoid sparking at the time of commutation of a section. The general discussion of the value of λ to effect this has not yet been attempted. For the present λ must be regarded as independent. The general equation of the characteristic surface becomes, for a continuous current machine,

$$l_1 f_1\left(\frac{\nu_1 \nu^2 z}{A_1}\right) + l_2 f_2\left(\frac{\nu_2 z}{A_2}\right) + l_3 \frac{z}{A_3} + l_4 f_4\left(\frac{z}{A_4}\right)$$
$$- 4\pi n_2 x - 4\lambda m y$$

λ being reckoned positive when the displacement is in the direction of rotation.

If no current passes through the armature, $y = o$ and ν_2 may be taken as constant and determined by experiment. The equation may then be written

$$l_1 f_1\left(\frac{\nu_1 \nu_2 z}{A_1}\right) + l_2 f_2\left(\frac{\nu_2 z}{A_2}\right) + l_3 \frac{z}{A_3} + l_4 f_4\left(\frac{z}{A_4}\right) - 4\pi n_1 x$$

which is the equation to the characteristic curve of a shunt wound or separately excited machine, and determines the induction for all values of the exciting current. Having determined the characteristic when $y = o$, the characteristic surface can be determined therefrom by considering the form of ν_2. (See J. and E. Hopkinson. *Trans. of R. S.*, part i., 1886, p. 334.)

It has been assumed that the sections of the armature are the only conductors in the field, or that the armature is so constructed that no currents circulate in the iron. This in the best machines is only partially attained. The effect of such currents on the characteristic surface is the same as increasing the current in the armature. If the lead is negative, the induction is increased both by the current in the sections of the armature and in the iron; but such a negative lead must give rise to destructive sparking as the sections will be commuted in a strong field.

ABSTRACTS AND EXTRACTS.

MAN'S CREDULITY.

KEELY ONCE MORE.

At a meeting of the stockholders of the Keely Motor company in Philadelphia, yesterday, a report was read which was said to be a complete review of the inventor's efforts and experiments as far back as 1882. We have read a synopsis of this document, and are forced to the opinion that it is very far from being a "complete review" of what Keely has done during these memorable five years. It does not half do him justice. He has during that period made a series of discoveries which were so remarkable that neither he nor anybody else has ever been able to define them in intelligible language. No man could read or hear the definitions given of them without becoming convinced that things which it put such a strain upon the powers of language to define must be wonderful in some way or other. We propose to compile a review of Keely's work during these five years, in order to counteract the injustice done him by the document read yesterday.

There had been hints of a great discovery by Keely early in 1875, but little definite was known until he published a card, about the middle of June, 1882, in which he said that he had reached a point in his experiments at which he could safely communicate his secret. He declared that he had discovered a great natural force, denominated by him an "etheric force," which exercised a pressure of 25,000 pounds to the square inch. How he obtained the force he did not make entirely clear, but so far as could be made out from his language he generated it by the comparatively simple process of pouring a pail of water into a hole. He announced that the mechanical appliance for using the force was "vibratory in character," and that he was about to get a patent on the discovery. He never did get it, and we presume the reason was that a patent was refused on the ground that the art of pouring water through a hole, having been known to man from the earliest times, was not an invention of Keely's. As for the force itself, he could not get a patent on that without disclosing it, and he could not disclose it because of the inadequacy of human speech to convey an idea of it. It was one of those mysterious agencies which could not be disclosed to the senses.

Keely's card did not satisfy some of the stockholders who had put $150,000 into the discovery, and they applied to the courts and obtained a judicial order directing him to disclose the nature of the invention and get a patent for it. A scientist named William Boekel was appointed to receive the secret. It was about two months before Mr. Boekel was able to comprehend what Keely was communicating to him. After seven weeks of constant revelation he declared that he was still unable to understand the discovery, and was induced to think that "recognized mechanical sciences cannot reach the thing." A week later, however, he filed a report in which he declared "unhesitatingly" that Keely had discovered a "new force of motive power,"

which he described as a "substance evolved by him through the instrumentality of his structure." This substance was a "vaporic or etheric force," and possessed "properties peculiar to itself and wholly phenomenal in character." "Time, patience, the closest attention," and the "study and application of vibratory forces" would be necessary not only to permit Keely to "perfect its utilization," but to "give such technical descriptions thereof as to meet the requirements of the law, as the condition of obtaining valid letters patent." Mr. Boekel's report was chiefly useful in showing that Keely's eight weeks of revelation had resulted in making Boekel's language as unintelligible as that of Keely himself, and this was a demonstration that a phenomenal force of some kind had indeed been discovered.

In December of the same year, Mr. Boekel communicated further on the subject to the stockholders, saying that the secret was in a fine condition, that the force had been utilized by Keely in an engine which "disintegrated" water so that its "molecular structure was broken up," and "therefrom was evolved a permanent expansive gas, vapor, or ether, which result was produced by mechanical action." The stockholders were unable to understand this, but were told that they would understand it when it was applied, as it soon would be, to a train of cars on the Pennsylvania railway. There was a long silence after this meeting, probably due to the mental exhaustion of the stockholders from attempting to understand the language of Boekel and Keely. In November of 1883 some of the stockholders became restless and talked about sueing Keely, but were quieted by the information that no good would come of it, since he alone possessed the secret, and as he was unable to make anybody else understand it, the company would simply destroy its own property by bringing suit against him and stopping his work.

The year 1884 was a very active one with Keely. He sent out a circular in February, in which he said he was able "to state positively (as regards the mechanical) that the first of the coming month will find all thoroughly completed, and there will be nothing left but setting up the transitive process, when all labors will terminate, preparative to operating and showing up the specific qualities of the perfect vibratory engine." The only point upon which there was doubt was as to the time necessary for "the line of graduation." This might take days, or weeks even, but he was sure that the "final issue was nigh at hand." About a month later announcement was made that all the "subordinates" who had been engaged for years in the construction of the motor had been discharged because their work was ended, and that Keely from that date would be shut up alone with the motor, and would devote all his energies to "focalizing and adjusting the vibrators." This, the world was assured, was an extremely delicate operation, which no living man except Keely could perform, but it would be mere child's play for him, and would end so soon as he obtained "one revolution."

Keely remained alone with the motor from March till September, when he emerged with the startling announcement that he had abandoned temporarily the work of "adjusting and focalizing the vibrators," and had invented a gun which would be used to demonstrate the power of the "force" or "etheric vapor." He held an exhibition at Sandy Hook soon afterwards, when ordinary scientific people declared that the "etheric vapor" was nothing more nor less than compressed air, but Keely said he would put these scoffers to shame very shortly by constructing two engines, one of 250 and the other of 500 h. p., and run them both by "etheric vapor." He said his principal difficulty had been to "bridle the force," but he had got it under control at last.

A period of quiet followed till June, 1885, when Keely held an exhibition in Philadelphia, and astonished everybody by bringing out the motor in still another form. This time it was an "Inter-Etheric Liberator," which was operated by an extraordinary combination of a "tuning-fork," a "fiddle-bow," a "disintegrator," "resonators," "wave-plates," "electric conductors," "confined vapor," and the "suction of Keely's mouth." Everybody who witnessed the exhibition was so dazed that he could not talk intelligibly, but that of course only showed once more what an inventor Keely was. All that the eye-witnesses could say was that when Keely, by applying his mouth to a thick tube, had established a "partial vacuum," and then going across the room had drawn a fiddle-bow across a tuning-fork, he "caused the 'Liberator' to act," and "things began to hum" at a tremendous rate of speed. A globe turned at the rate of a thousand revolutions a minute; a solid plank placed against its revolving periphery was torn into splinters; small leaden balls were shot out of a cannon; an engine was driven at a terrific rate of speed; and several other things were accomplished. But, as usual, language failed to explain how it was all done. In May, 1886, a similar exhibition was held with the same "Liberator," when a disturbance was raised by an ordinary scientist asking the privilege of performing the same experiments without a tuning-fork. Keely considered this request insulting, and the scientist was ejected. Keely said that within sixty days he would have an engine in operation and would take out his patents.

All has been quiet since till now, when Keely comes forward and says that new "phenomena have been unfolded" to him, opening a new field of discovery, and that he shall abandon the "etheric force," the "Liberator," and all other former forces, and shall conduct all his experiments with a new force, for which he has not an exact name, but the "basis of which is vibratory sympathy." He proposes the formation of a new company with a capital of $15,000,000. The old company has sunk many thousands of dollars in the "etheric force," and we presume that their "vibratory sympathy" is exhausted. Keely has at last hit upon the right name for his force. Its sole power consists in the amount of "vibratory sympathy" his experiments can arouse in the pockets of gullible capitalists.—*The N. Y. Evening Post*, Dec. 15.

THE DISEASES OF DYNAMOS.[1]

BY PROF. SILVANUS P. THOMPSON, D.SC.

CONSIDERING the widespread use of the dynamo-electric machine, and the mass of literature concerning it that has sprung up, it seems remarkable that no one should as yet have written upon the topic of the maladies to which such machines are liable, their treatment, cure and prevention.

Not once or twice has it occurred in the writer's professional experience to be called into consultation over some hitch that has arisen in the maintenance of an electric light installation where the experience of the engineer and the knowledge of the electrician in charge had failed to discover the cause of the breakdown, or suggest an appropriate line of action. Under such circumstances one cannot help comparing oneself to a physician called into consultation over a patient. And as a knowledge of the diseases of dynamos and their treatment form a necessary part of the complete training of the electric engineer, an attempt by a specialist to elucidate the subject and systematize it, may appropriately be brought before such a society as this, comprising as it does many electrical engineers.

Moreover, as some of the members of this society have had large and diversified experience in the construction, erection, use, maintenance and repair of dynamos, the writer hails this opportunity of inviting an interchange of expression from all members present respecting the causes that lead to the breakdown of dynamos and their prevention.

The diseases of dynamos, like those of human beings, may be classified under several heads, whether constitutional or acquired, whether curable or incurable, whether surgical or medical in the treatment required.

The constitutional diseases may arise either from defective design or imperfect construction. A ricketty constitution in a dynamo may result either from inherent badness in the forms of those parts which should give strength to the structure, in the employment of bad or faulty materials, or in bad workmanship. Diseases acquired as the result of overwork and of neglect, though classified as acquired rather than constitutional, are more likely to be developed where there is a constitutional weakness. The physician who is called in must have the eye to detect the constitutional taint, as well as the more obvious present causes of mischief. When called into consultation upon a human subject, the physician's first inquiry is as to the symptoms that present themselves. Perhaps a clinical examination is necessary to learn the whole of the symptoms in the case. The diagnosis of the case being completed, a course of treatment suggests itself, which course may be of several kinds. A surgical operation may be necessary, or perhaps bandages and poultices may accomplish all that is required. It may be proper to administer drugs; or in milder cases a change of climate or diet is all that is prescribed. Simple rest accomplishes wonderful cures; but in neglected cases long and careful nursing may be the only hope.

It may safely be said that at least four-fifths of the breakdowns that occur with dynamos—whether partial or total—arise from causes that are more strictly within the province of the engineer than in that of the electrician. On the other hand, many of the mechanical faults that develop themselves in the machine might have been avoided had the engineer possessed a better knowledge of the electric and magnetic conditions that obtain in the running of the machine. It is not often nowadays that armatures fly to pieces. That disaster has seldom occurred since good engineers took in hand the construction of dynamos, though it was, relatively to the number of machines used, a not unfrequent occurrence in the days when armatures were mostly designed by electricians who had little or no knowledge of mechanical engineering. On the other hand, any engineer will make a poor builder of armatures who does not understand the nature of the reactions that occur in the magnetic field—how a conductor carrying a current is subjected in the magnetic field to a mechanical force exerted upon it without any visible means of transmission. If he does not understand this, he will not grasp the necessity of so designing and constructing the armature and its spindle that the power applied to the spindle shall be conveyed directly to drive the peripheral conductors. He cannot realize that it is

1. Paper read before the Finsbury Technical College Old Students' Association, Nov. 29, 1887.

the copper wire, and not the iron cores, that primarily require to have the power applied to them. He may know that insulation is necessary, and that lamination of iron cores is necessary; but he may, for want of full electrical knowledge, apply both the insulation and the lamination in an entirely erroneous manner, and produce a dynamo that will break down directly it is put to any severe test.

Amongst the complaints to which armatures are subject are the burning-out of coils, the burning of the binding wire, and the breaking off of the conductors near the ends where they go to join the respective parts of the collector. The burning-out of coils is sometimes due to short-circuiting at the collector between two adjacent sections; but often it arises from short-circuiting in the armature itself. In armatures so constructed that the windings of one section lie partly over the top of those of another section this evil is more likely to occur than in those that are not so constructed. Short-circuit between an imperfectly insulated wire and the iron core beneath it is a frequent source of trouble, and this again arises either from bad mechanical work allowing the iron laminæ to become loose, or from the use of unreliable insulating materials. Sometimes armatures are destroyed by charring of the insulation, not in consequence of the overheating of any of the wires, but from the overheating of the iron cores. In such cases either the iron is not properly laminated, or else the insulating material between the iron laminæ has failed to insulate. The burning of binding wire clearly arises from want of compliance with the necessary and sufficient electrical conditions. The fracture of the armature conductors near the ends where they turn over to the collector—a most annoying fault when it occurs—appears to be partly mechanical and partly electrical. These conductors are, at this point, not supported laterally; any engineer would imagine that they were strong enough to stand any longitudinal or centrifugal force to which they might be subjected. Yet they have to withstand severe lateral forces, arising from the fact that they carry strong currents and are situated in a fairly powerful part of the magnetic field, which here extends beyond the edge of the polar surfaces. Hence they are each racked by a lateral force that comes upon them twice in every revolution; and which, moreover, must strain them severely whenever the current is suddenly cut off or turned on. The collector, or commutator, and its brushes are a fruitful cause of trouble. Brush-holders are rarely as substantial as they should be. The conditions of good mechanical work and good electric work are here somewhat antagonistic; but the mechanical work must be good, otherwise the best observed electrical arrangements will fail. The brushes must not slip or jump with the vibrations of the machinery. If they press too heavily, the surface of the collector will be torn into ruts; if too lightly, the edges of the separate sections of the collector will be bitten and rounded by sparks. The curious disease known as the occurrence of "flats" in the collector has been a source of puzzle and annoyance to many. In many cases the occurrence of a "flat" may be definitely traced to a more or less developed fault in some one section of the armature coil. A broken armature coil, the ends of which still touch against one another within their insulating sheath, may go unsuspected; but it may have the effect—by its increased resistance—in causing an increase of spark at the brush just as it passes through the position of commutation. Hence the corresponding bar of the collector will, at every half-revolution, be bitten into by a spark a little more than any other bar is bitten into, and so become flattened as compared with the proper peripheral curvature of its fellows. "Flats" do not, however, always arise from this cause. It has been observed that a "flat" may break out on one bar of the collector; and on turning down the surface of the collector so as to remove it, a "flat" breaks out on another bar of the collector. A "flat" may arise from a flaw in the metal of the bar, which passing under the brush, gives rise to a spark that bites away the metal a little further to right and left, and so spreads along the bar until the whole surface of it is more or less bitten away. A little more pressure on the brush, and a better mechanical holding of the brush, are remedies not to be despised. The collector is the one part of the machine most likely to give trouble; it is rarely made large enough; years of experience have not yet given any decisive answer to the question, what materials it should be made of? Whilst English makers are almost agreed upon using either hard-drawn copper or else some kind of hard bronze with mica insulation between the bars, Messrs. Siemens & Halske have this year abandoned these for iron bars with air gaps between. Before mica was in general use asbestos was not unfrequently employed, and with curious results. At one time the writer was working with a small Siemens shunt dynamo, giving on open circuit about 80 volts One day it gave only a little over 70, though the speed was normal. The next day it was under 70, the next it refused to excite itself. The circuits were tested out, as a fault in the shunt, increasing its resistance, was suspected; but there was nothing found wrong. When separately excited from accumulators, it, however, only gave 15 volts on open circuit. In vain the brushes were replaced and the brush holders cleaned. There was plenty of magnetism, for the armature got hot; yet no sparks, or next to none, at the brushes, even when short-circuited. Suspecting that some of the armature coils were short-circuited, an attempt was made to test the resistances between bar and bar of the collector, but without any very decisive results, owing probably to the roughness of the test. However, there were noticed some slight inequalities, which gave a clue to the cause of trouble. On examination it was found that nearly every one of the collector bars was more or less short-circuited to its neighbor by a charred mass of carbonized oil imbibed into the asbestos which formed the insulation. It was dug out with a penknife and replaced by another material, when the dynamo was restored to its proper activity. This vice has been of not unfrequent occurrence. Only a few weeks after the occurrence named the writer received an urgent call to go to a town in a distant part of England, where a dynamo refused to work. Being unable to leave home that day particular inquiries were addressed by telegraph, and yielded the information that it was a Siemens shunt machine, that all the circuits tested right, but still the machine would not excite itself. Instructions were despatched to dig out the insulation between the collector bars, and the remedy proved effectual. Obviously, in such cases, oil ought not to be used on the collector, but only asbestos dust or French chalk. The writer has subsequently learned that a very similar trouble sometimes arises in certain machines that have collectors so constructed that there is a cylindrical cavity beneath the collector bars into which oil from the lubricators at the bearings may drain, and in which a charred mass ultimately forms, short-circuiting the entire collector. Another cause of trouble is the small metallic dust which flies from the collector when the brushes press so heavily as to produce ruts, entailing consequences partly mechanical and partly electrical that may end in a breakdown.

Amongst other faults of armatures that give trouble there is a purely mechanical one, arising from want of knowledge on the part of the electrical designer, namely, that of not being properly balanced. Every engineer worthy the name knows that a thing so balanced as to stand in any position is not necessarily balanced for running; that a four-pound weight at three inches from the axis of rotation, though balanced statically by a one-pound weight at twelve inches from the axis, is not balanced by it dynamically, for the moments of inertia about this axis are not equal. On the contrary, a four-pound weight at five inches is balanced dynamically by a one-pound weight at ten inches from the axis. A machine that violates dynamical principles can never be satisfactory. Short bearings where long ones would be appropriate; a high-speed machine where a low-speed machine is the only suitable sort (for example, on shipboard); inside bearings where outside ones ought to be used, and *vice versa*—all these things have been and may still be answerable for breakdowns. So much the more reason is there for the electrical engineer to be engineer first and electrician afterwards. Not that electrical knowledge is to be despised. The writer once heard an experienced engineer who had been put in charge of a dynamo which was lighting some arc lamps, and doing its work badly, declare that the trouble arose, not from an insufficient supply of current—he did not dispute the quantity of the current—but from the current being of a rather poor quality. There were, in point of fact, too many lamps in the circuit. Again, it is a fact furnishing food for reflection that in those electro-plating shops in London where dynamos are used, the practical men in charge almost invariably hold the firm opinion that they are not getting the proper current unless they can see sparks at the commutator. They therefore so adjust the brushes that they get a good blaze. Sparking at the commutator or collector is a symptom of disease in a dynamo, just as truly as an outbreak of pustules is a symptom of disease in the human subject.

In the field-magnets vices of construction are more frequent than acquired defects. Field-magnet coils are sometimes wound on frames that are loose, or the coils are badly insulated. When the frames are loose the resulting vibration not unfrequently causes the ends of the wires to snap off short. If there is a single short-circuit between coils and iron-work in the field-magnet, then a single short-circuit at any other point—armature coils, collector bars, brushes, brush-holders, or terminals—may work dire disaster. A little Brush machine lent to the Finsbury Technical College by the Anglo-American Brush Corporation had its commutator segments completely ruined in a few minutes by a curious double fault of this kind, which defied detection for several days. There were two short-circuits, neither of which, in itself, would have done any harm whatever; but the iron support that held the rocker for one pair of brushes was so fixed by screws as to make a cross connection that short-circuited two pairs out of the four pairs of coils on the armature. A short-circuit between coil and iron core of the field-magnet is more likely to arise in shunt machines or compound machines than in series-wound ones, owing to the much higher electromotive force of the self-induced extra current if the shunt-circuit is from any cause opened. Alternate current dynamos are liable to develop different kinds of faults from those to which direct-current machines are liable. They sometimes exhibit a curious pulsation of a determined slow period in their currents. The cause for this is probably purely mechanical. Again, machines for constant current are liable to disorders of a different nature from those of machines intended for constant potential work. The latter are

more liable to overheat; the former are more troublesome in respect of sparking, because of the very great variations in the position of the neutral point.

Very little attention seems to have been paid to the question of the goodness or badness of insulating materials for resisting being broken down under working conditions entailed by damp, dust, and oil. Under such conditions it does not in the least follow that the material showing the highest insulation tests is the best. Very few dynamos will show, even when new, an insulation-resistance between iron work and copper work amounting to anything like one megohm. Yet a dynamo that showed only 10,000 ohms of insulation-resistance and mechanically resisted being broken down, would be preferable to one the insulation-resistance of which was a hundred megohms, if that high resistance were secured by employing brittle materials, or materials that were destroyed by the presence of oil. Whether mica is in all cases preferable to asbestos, Willesden paper to vulcanized fibre, or shellac varnish to a solution of india-rubber, or what other insulating materials should be prescribed in preference, can only be ascertained by a careful study of the failures that have from time to time arisen when one or other was employed.

Only by the study of the malady as it arises can the proper treatment be discovered to prevent its recurrence. In short, by the proper study of dynamo-pathology, we may arrive at a fuller knowledge of dynamo-therapeutics.

DISCUSSION.

Mr. Jones, referring to pulsation on alternate current circuits, said that in one case in London, where two such machines were used, he had traced a very troublesome pulsation to the collector, which had worn oval. The fault was removed by turning up the collector.

Mr. Esson was of opinion that engineering faults were generally the cause of breakdowns. Speaking of the relative merits of armatures in which the wire was supported by metal projections, and of those where the wire was held on merely by friction, he stated that he had never seen a fault from the wires being attached in the latter manner. The breaking of wires leading to the commutator was more common in motors than in generators. He thought it was due to the spindles bending. For commutators he recommended gun-metal, where great pressure was required to prevent vibration, as in motors on tram-cars; in other cases hard-drawn copper, lubricated with vaseline. He thought that unequal sparking of brushes was due to the field being made unequal by the presence of masses of iron about one of the poles.

Mr. Mordey thought the fault of the breaking of wires near the commutator was an obscure one; it had never been quite satisfactorily explained. He recalled a paper published some five years ago by Hefner von Alteneck, in which the fault was discussed, but left unexplained. Professor Thompson's suggestion was a good one, but he thought that the first effect of the movement of the wires in the fringe of the field should be to give them all an inclination in one direction. This did not occur, and he thought, therefore, that Professor Thompson's suggested explanation was not quite satisfactory; neither did Mr. Esson's quite fit in with many cases where the fault had been observed—that was in the steady running of dynamos. The fault had never occurred in Brush or Victoria dynamos. The pulsation in alternating current dynamos was often noticeable. In one large installation in London, where the dynamos were driven direct, the pulsation was very marked, and appeared to be too quick to correspond with the speed of the engine, and too slow to be due to the actual alternations. Referring to commutators, he said that various lubricants had been recommended. Sir William Thomson was credited with advancing the claims of treacle for this purpose. He thought that the lubricator was the least important matter in successful collection; nor was it very important how the brushes should be made, provided they were not too thick. Carbon had been recommended for brushes, but he thought carbon should be reserved for the arc lamps. The unequal sparking and heating of brushes had often been noticed, and he was inclined to attribute it to an effect similar to that which occurred in arcs, where one electrode got hotter and burnt away faster than the other. He asked others to try, by reversing the polarity of the magnets, whether they could confirm or disprove him. The difficulty was that sparking in modern dynamos was usually very slight, and convincing results were difficult to obtain. The effect of any inequality of the distribution of the fields would be removed by reversing the polarity of the magnets. After describing some simple methods for localizing faults in low-resistance armatures—matters in which ordinary bridge and other measurements were of no use—he referred to the question of insulating materials, on which Professor S. P. Thompson had made some observations. Vulcanized fibre was a very unsatisfactory insulator. The material itself was probably good, but he thought the manufacture could not be carefully conducted, as the substance frequently broke down in a way which seemed to indicate that metal filings or other foreign substances were rolled into the sheets. While acknowledging that dynamos were liable to suffer from many diseases, he thought they should not be too harshly blamed, and mentioned a case where, of two similar machines, one was always found to require a higher speed of the engine and apparently to absorb more power than the other. He traced the loss to a friction clutch which had been allowed to become covered with oil, and was slipping and absorbing about 18 h. p.

Mr. D. Pearce said that he had found the insulation of some Siemens dynamos was very low, the paint used having quite soddened the cotton with oil. He mentioned a case of unequal heating of brushes, where the positive brush always wore several times as fast as the negative. The fields had been reversed, but without effect.

Mr. Sumpner said that, in taking the curve of a Ferranti dynamo, he had found that there was an occasional departure from the sine curve, caused by an inequality of the winding.

To this Mr. Mordey objected that, as all the armature coils were in series, all the curves must be alike, any inequality affecting the curve similarly at every alternation.

Professor Thompson remarked that an inequality in the armature winding and another in the field would account for the discrepancy, which would then occur once in every revolution.

After some remarks from Mr. Howard Swan, Mr. Dickson, and other members, and from Mr. Pettigrew, who occupied the chair, Professor Thompson replied. He said that the thickness of brushes should be such that the current should have time to die out of the coil, under the brush, to start again, and to come up to the strength of the main current before the coil was again thrown into the circuit. He did not quite give up his idea that the breaking of wires was due to the magnetic field. The sudden putting-on of the current in motors would account for the increased occurrence of the fault in them. In motors the brushes might be wider than in generators. Alteneck had told him that the fault had been entirely got rid of by connecting the segments to coils 90 degrees removed from them. He thought, and had previously pointed out, that unequal fields were often a cause of sparking, and that on this account double magnets had an advantage.

A cordial vote of thanks to Professor Thompson for his interesting and instructive paper terminated the proceedings.

A TALK ON TRAMWAYS.

At the meeting of the New York Electrical Society, held on Nov. 30th, Mr. Holroyd Smith, of London, gave a "Talk on Tramways," in which he treated the subject of street railroads, first in a general way, and then with special reference to the electrical method. In beginning his address, Mr. Smith said that too much attention cannot be given to the fact that in electrical railroading the electrician occupies the second place to the engineer, and that the past failures in electric railroading have been due to the fact that electricians, pure and simple, have gone into the domain of engineering without sufficient knowledge to guide them. In other words, the electrician must not expect to succeed in working tramways unless he studies the engineering problems as well. Mr. Smith, in taking up the subject generally, drew attention to the fact that American railroads, or tramroads, were the necessary outcome of the generally bad ordinary roads, whereas in England the roads are uniformly good. While in America the centre bearing rail is employed almost universally, in England, and abroad generally, such a rail would not be permitted, and recourse must be had to the grooved rail. Hence, while with American cars and rails the coefficient of traction amounts to about only eight pounds to the ton, the English rail requires 23 pounds to the ton, so that these things must not be lost sight of in designing cars. It will thus be seen that conditions vary considerably in different countries, even when seemingly they are quite alike. Mr. Smith asserts that the increased power claimed for the driving motors is due to the overestimation of the power required to move the car.

Mr. Smith then entered into the consideration of traction by horses, compressed air, steam and cable, and deplored the fact that while in England the statistics of running expenses of horse car lines were well known and published in Duncan's *Tramway Manual*, we had no such source of information, and it was with the greatest difficulty that any reliable figures could be obtained with regard to the subject on American lines. Mr. Smith stated that as a rule in England a 2-horse car running for 14 hours a day required 10 horses. These horses cost £30, and had an average life of three years. In discussing the question from the electrical standpoint, Mr. Smith drew attention to three essential points that have to be considered: 1. Safety to the public. 2. Efficiency. 3. Economy.

Taking up the storage battery first, Mr. Smith held the position that even if the battery could be successfully worked, it would cost one-third more to equip and run a line on this system than to put down a conduit, and especially would this be the case where traffic is very heavy. Mr. Smith was of the opinion that of the various systems the overhead system was the best, taking all into consideration; but the great danger in its use lay in the tendency to do slipshod work. The difficulties met with at crossings and switches in railway work where conductors of opposite polarity met in a horizontal plane are overcome by placing the conductors in a vertical plane, so that even if contact

does occur it can only happen between two positive or two negative conductors. Mr. Smith finally described a new method of his own which was designed to overcome all the objections to both the overhead and underground circuits, and which, without the use of the storage battery, is arranged to supply the motor on the car with electricity. This system, which was only hinted at by the speaker, will no doubt attract some attention in the future.

In the discussion which followed, Mr. T. W. Rae spoke of the experiments made on cars in this city by Mr. C. E. Emery, the well-known engineer, who found that the coefficient of traction was 12½ pounds per ton; and General Q. A. Gilmore states that the general average for the whole country is 16⅔ pounds per ton.

Mr. R. G. Blackwell, whose opinions on this subject are well known, deprecated the use of the storage battery entirely, and, in replying to a question, remarked that the delay in the construction of the Fulton street road in this city, undertaken by the Bentley-Knight company, was due to legal complications; and that all the material required for the road was in store in this vicinity, ready to be applied at the earliest notice.

Mr. C. O. Mailloux in replying to Mr. Blackwell, detailed the experiments which are now going on upon the Madison avenue line in this city, on a car equipped with 120 cells of Julien storage battery, and which ran from 85th street to Harlem Bridge and back, on a run of 40 miles, with a drop of but two volts. Mr. Mailloux stated that the Brussels Tramway Co. are now operating 10 cars of this system and that before many months have elapsed New York will see as many storage cars in operation. Mr. Mailloux drew special attention to the fact that storage batteries were well adapted to long lines on account of the large conductors required with the overhead and underground systems, where the drop of potential has to be made as small as possible.

Mr. Holroyd Smith confirmed this statement of Mr. Mailloux, but he still claimed that the use of the storage battery was only a transient one. In reply to a question by Mr. Davidson as to whether a conduit had ever been operated in this country, Mr. R. G. Blackwell referred to the experimental line operated in Cleveland on the Bentley-Knight system, and carried on through snow, ice and water without trouble. Mr. Smith also confirmed this fact, and stated that the last winter had been most severe in Blackpool, England, where his road was in operation, but notwithstanding this, the current had practically not stopped in three years since the road went into operation.

After the close of this discussion, Mr. G. F. Harris brought before the society a slip of the cable record made by one of the first Thomson siphon recorders, on the cable between Vigo and Penzance, and also made a few explanatory remarks relative to cable work.—*The Electrical World.*

THE BESSBROOK AND NEWRY TRAMWAY.

BY DR. E. HOPKINSON.

THE following is an abstract of a paper read at the ordinary meeting of the Institution of Civil Engineers on Tuesday, the 6th of December, by Edward Hopkinson, M. A., D. Sc., A. M. I. C. E.:—

"Although a number of electrical tramways had been constructed in the United Kingdom during the last few years, there had hitherto been no attempt at the regular haulage of minerals and goods, nor at the operation of cars larger than the ordinary tramway type. Probably in no case had the effective power of any single motor exceeded about 4 h. p. The principal object of the present paper was to describe the construction and to discuss the working of the Bessbrook and Newry Electrical Tramway, which had been designed for the haulage of heavy goods as well as for passenger traffic. The length of the line was rather more than three miles, with an average gradient of 1 in 86, the maximum gradient being 1 in 50. According to the conditions of the contract ten trains were to be run in each direction per day, providing for a daily traffic of [illegible] tons of minerals and goods, and capable of dealing with 200 tons in any single day, in addition to the passenger traffic. The electrical locomotive was to be capable of drawing a gross load of 18 tons on the up-journey, in addition to the tare of the car itself and its full complement of passengers, at an average speed of 6 miles per hour, and a load of 12 tons at an average speed of 9 miles per hour. Also, the cost of working, as ascertained by six months' trial, was not to exceed the cost of steam-traction on a similar line. The line was formally taken over by the company, as having fulfilled the conditions of the contract, in April, 1886, and had since been in regular daily operation. It was worked entirely by water-power, the generating station being adjacent to the line at a distance of about one mile from the Bessbrook terminus. There were two generating dynamos of the Edison-Hopkinson type, driven by belting from the turbine shaft, which was extended into the dynamo shed for the purpose. The turbine could develop 62 h. p., and each dynamo was intended for a normal output of 250 volts 72 amperes, though they were capable of giving a much larger output. The current was conveyed to the locomotive cars by a conductor of steel, rolled in the channel form, laid midway between the rails, and carried on wooden insulators nailed to alternate sleepers. The conductor was not secured, but was simply laid upon the insulators, which fitted into the channel, and while allowing for longitudinal motion to compensate for changes of temperature, held it laterally. At one point the line crossed the county road obliquely, the crossing being 150ft. in length. In this case the conductor on the ground level was not feasible, and an overhead conductor on Dr. John Hopkinson's system was substituted, by which the collector on the car consisted of a bar only, which passed under the supports of the overhead wire, and made a rubbing contact with its under surface. This system had been found to give very satisfactory results in practice.

"The locomotive equipment of the line consisted of two passenger cars, each provided with a motor. The body of the car was carried on two four-wheeled bogies, the motor being fixed on the front bogie, so as to be entirely independent of the body of the car. The longer of the two locomotive cars was 33ft. in length, and was divided into three compartments, the front one covering the motor, and the two others forming first and second class compartments, together accommodating 34 passengers. The front bogie carrying the motor had an extended platform, projecting beyond the body of the car, and communicating by a slide door with the dynamo compartment, thus giving the driver direct access to all parts of the driving machinery, which was at the same time entirely boxed off from the passenger compartments. The weight of the locomotive, including the dynamo, was 8¼ tons.

"Apart from the electrical working of the line, an important and novel feature was the plan by which the wagons used on the line could also be used on the ordinary public roads, so avoiding the necessity of trans-shipment, and enabling goods to be loaded at the wharves and drawn to the line by horse-power and again delivered where required. The plan was originally suggested by Mr. Alfred Holt, M. Inst. C. E. of Liverpool, and was embodied in the Lancashire Plateway Scheme, for which a bill was lodged in the autumn of 1882 and subsequently withdrawn. The idea had been worked out in a practical form with great success by Mr. Henry Bancroft, of Newry, one of the directors of the Tramway company. The wheels of the wagons were constructed without flanges, with tyres 2¾in. wide, which was sufficient for use on ordinary roads. Outside the tramway rails, which weighed 41.25lb. per yard, second rails were laid, weighing 23.75lb. per yard, with the head ⅞in. below the head of the larger rails. The flangeless wheels ran upon these lower rails, the ordinary rails forming the inside guard. The front part of the wagon was supported on a fore-carriage, which could either be pinned or allowed freedom of motion, as in an ordinary road vehicle. There was a single central coupling arranged to engage in a jaw on the fore-carriage, so as to guide it when not pinned. Shafts were attached to the fore-carriage when the wagon was to be used on the ordinary roads. The wagons were of sufficient strength to carry a load of 2 tons, and their weight without the shafts was 23¼cwt. Experience had shown that the wear and tear, both on the wheels and rails, was not excessive, and that the traction did not much exceed, if at all, that of ordinary trucks with flanged wheels. No difficulty had been found with the [illegible]-traction on ordinary roads, and the taking on and off was conducted with great rapidity.

"Each locomotive car was fitted with an Edison-Hopkinson dynamo, which was geared by means of helical-toothed wheels, and a chain to one axle of the bogie. The special construction of driving chain, rendered necessary by the severe conditions under which it had to work, was fully described. The trains were commonly composed of one locomotive car and three or four trucks; but frequently a second passenger car was coupled, or the number of trucks increased to six. Thus a gross load of 30 tons was constantly drawn at a speed of six or seven miles per hour, on a gradient of 1 in 50. The cars could be reversed by reversing the current through the motor without change of lead, but as there was a loop at each end of the line, reversal was only required when shunting in the sidings. The terminal loop-curves were 55ft. radius only, but these were traversed by the long locomotive cars with perfect ease, to which the method of carrying the motor-dynamo on the bogie largely contributed."

The author concluded the paper with a discussion of an extended series of experiments to determine the efficiency of the whole combination under various conditions, and the distribution of the losses. The results were illustrated in a graphic form by a series of curves. Under average conditions of working the total electrical efficiency was shown to be 72.7 per cent., the losses being distributed thus:—

Loss in generator	8.6	per cent.
" leakage	5.7	"
" resistance of conductor	6.6	"
" motor	7.7	"

The friction of the bearings in both generator and motor, and the power lost in the driving gear, were excluded from these results.

In an appendix to the paper the cost of the electrical equipment of the line was summarized, and the cost of haulage per train mile was shown to have been 3.3d. over one period of five months, when the goods traffic was light, and 4.2d. when the goods traffic was heavier. Since the opening of the line the locomotive cars had registered a train mileage of 40,000 miles, and the tonnage had exceeded 25,000 tons, and the number of passengers 180,000.

CORRESPONDENCE.

NEW YORK AND VICINITY.

Another Competing Telegraph to be Established.—A Second Telephone Conference.—Ex-Senator Kiernan's Tribulations.—An Electric Light War in New Brunswick, N. J.—Capital Punishment by Electricity.—Electric Mail Despatching.

IN spite of the recent experience of the Baltimore & Ohio Telegraph Co., a movement is already on foot to establish a new system of competing telegraph lines. The project bears the imprint of being feasible, but the plan is not new. It is based upon the leased wire business, which has of recent years proved a reliable source of revenue and such wires could be utilized for ordinary telegraph service at night. This was the scheme upon which the Mutual Union Telegraph Co. was organized. The projected company is expected to undertake a general press service to occupy its wires at night. It is also proposed to place the wires underground through cities in order to avoid obstruction by the municipal authorities. All of this can be accomplished if the requisite amount of money can be secured. It appears quite natural to suppose that the time may come when it will be impossible to raise funds for the construction of opposition telegraph lines, but it is evidently still in the dim future.

The interchange of opinions at the telephone cable conference held in September at the new telephone building was productive of so much valuable information, that another conference was recently called to take up and discuss other practical subjects. Among those in attendance on December 21st, were Thomas D. Lockwood, W. J. Denver and Isaiah H. Farnham, of Boston, Henry Metzger, of Pittsburgh, W. D. Sargent, of Brooklyn, E. D. Hall, A. S. Hibbard, J. A. Seely and Jos. P. Davis, of New York. The conference was strictly private, but it is believed to have been devoted to the question of switch-boards and the administration of telephone exchange affairs in general. The secret character of these conferences is advantageous in many respects, as those present feel at liberty to speak freely as to the merits of various descriptions of material and apparatus, as well as the general policy of telephone management without fear of its effect on the outside public.

Ex-senator John J. Kiernan has not cleared himself of the financial difficulties in which he has become involved. Suit has been brought against him by the Columbia Rolling Mill Co., of New Jersey, for the amount of certain promissory notes which he gave in exchange for capital stock of the company. Full information of the affair was sent out over the tape of the rival system operated by the Stock Quotation Co., which appears to have made serious inroads upon the once flourishing news agency of Kiernan and Co.

There is another electric light war in New Jersey. This time it is at New Brunswick, where the gas company is striving to obtain a franchise which will enable it to place electric lights in every street and alley in the city, and it also proposes to erect iron posts. The electric light management claim that this is merely an attempt to crush their enterprise, while the gas people retort that if they had agreed to pay down a certain sum of money when the electric light company was first talked of, it would never have engaged in business.

The commission which was appointed two years ago to inquire into the advisability of adopting some more humane method of capital punishment than hanging, expects to complete its report for the new state legislature early in January. It is authoritatively stated that the members have finally agreed to recommend electricity for the purpose. It is certainly open to question whether this branch of electrical development will increase the popularity of electric lighting for general use, as the frequent fatal accidents are not to be readily explained to the entire satisfaction of the public.

There is a scheme hatching in Baltimore for an electric elevated mail railway, which if successful is expected to revolutionize the transportation of light packages. The time occupied between Baltimore and New York for this service is estimated at one and one-quarter hours. The prompters of the enterprise are, as usual, exceedingly reticent. The most that has been done towards starting the system is the filing of a caveat, and organizing what is known as the Electrical Despatch Co.

NEW YORK, Dec. 21, 1887.

PHILADELPHIA.

Public Electric Lighting Questions.—The Philadelphia Bell Telephone Co. Still Seeking Underground Permits.—A General Inquiry Into Underground Franchises.—The Franchise of the Penn Electric Light Co.—The Affairs of that Co.—Opinion of City Solicitor on Underground Franchises.

THE peculiar relations existing between the various electric light and telephone companies, and the reasons for the high cost of the electric lights furnished to the city, are likely soon to have a little additional light thrown upon them. President Lawrence, at a recent meeting of city council's finance committee, promised to ventilate the latter subject. A deficiency in the appropriation for electric lighting was under consideration, and Mr. Lawrence drew from chief Walker the statements that the present contracts for the lighting would expire on January 1, and that the average price per lamp per night paid by the city is 55 cents. This was enough for the president of common council, and he remarked impressively:

> Then I desire to inform this committee and the citizens of Philadelphia that the city of York, Pa., pays for electric light 16 cents per lamp per night, the city of Columbia pays 18 cents, and the city of Lancaster 22 cents. I also desire to state that a Philadelphia company which is charging us 55 cents per night has offered to furnish the light for York for $7 per month per lamp. I do not propose to give one dollar more for lighting the streets of Philadelphia than is paid by these little inland towns. When this appropriation comes up in councils I will ventilate the subject.

Nearly all the companies which supply lamps for city lighting are in the Electric Trust. When this combination was formed last winter it was reported that it intended to put up prices on the city. This was not done at the time, owing to a strong protest, but it was said that the prices for 1888 would probably be advanced. If this shall be attempted some breezy developments may be expected.

The Penn Electric Light Co. maintains harmonious relations with the Trust. The two companies work in such perfect harmony that this may explain why no other electric light or underground companies can get any ordinances through city councils. The Keystone and Edison Electric Light companies have for a long time been applicants for franchises before councils, and their applications have been in the hands of a sub-committee of councils' electrical committee since June last. The Edison company, having recently made terms with the Penn Electric Light Co., is not now particularly anxious about any concessions from councils.

In this respect it differs from the Bell Telephone company, which has for a long time had an ordinance pending before councils, and has been desirous of pushing it through, that it might open streets and put its wires underground. It has been said that the Penn company is anxious that the telephone company should use its (the Penn company's) conduits for its wires, as this would insure a handsome revenue. The telephone company has replied that difficulties of electrical induction would make it almost impossible to use electric light and telephone wires in the same or adjoining conduits, and the matter hangs fire. Conferences have been held between the representatives of the two companies for several days past, and this astounding statement was made by a member of city councils yesterday: "An effort has been made to convince the Penn people that the Bell and Western Union companies cannot use the Penn conduits. If it should not prove successful there will be war and some fun."

The entire subject of the legality of the franchises held by the various underground conduit companies will be inquired into by the councils. The initiatory steps were taken December 6th, at a meeting of the law committee of councils. The sub-committee, to which had been referred in June last the resolution authorizing it "to investigate the legality of certain electrical ordinances passed by councils," made a report embodying the opinion of the city solicitor, which was read before common council a few days since. The sub-committee, through Mr. Scott and Mr. Anderson, reported the following as a substitute for the original resolution, which had been referred to it in June last, and requested that it be referred to councils with a favorable recommendation:

> Whereas the city solicitor has given an opinion, which is hereto annexed, from which it appears that all ordinances hitherto passed by these councils granting to others than corporations incorporated under the laws of the state of Pennsylvania, or who have not complied with the corporation laws of this state in regard to foreign corporations seeking to do business in Pennsylvania, permission to lay a line or lines of telegraph, telephone and electric light wires, construct and maintain electrical conductors, conduits, cables, manholes, etc., under the streets and highways of the city of Philadelphia are ultra vires and void; therefore be it
>
> *Resolved*, by the select and common councils of the city of Philadelphia, That the committee on law, by and with the advice and co-operation of the mayor and city solicitor, be and it is hereby authorized and directed to investigate and ascertain what ordinances are ultra vires, and to take such steps as will prevent the exercise of the powers granted in said ordinances, and such other steps as may be deemed necessary in the premises.

After some discussion the preamble was amended so as to make it refer to such companies as "have not complied with the corporation laws of the state in regard to foreign corporations seeking to do business in Philadelphia," When this had been incorporated in the resolution it was unanimously agreed to report it to councils with a favorable recommendation.

Chairman Etting will make his report to select council, and the first fight will take place in that chamber. Should it pass that body a most determined opposition will be made against it in the lower chamber, where the friends of the underground conduit companies are particularly strong.

The opinion of city solicitor Warwick, concerning the franchises of the Penn Electric Light Co., has given rise to considerable discussion among the stockholders of that corporation, the list of which includes many public men, politicians and well-known men about town. The stock is also held heavily by storekeepers along South street, who expected to reap a harvest by their investment. Most of these persons paid 75 cents and $1 per share for their stock. It is now held at 17 cents per share.

The opinion of the city's law officer was considered to be of so much importance that a special meeting of the directors of the Penn company was held to discuss the situation. Among those present were Messrs. James McManes, David H. Lane, tax receiver Henry Clay, George E. Vickers, and R. H. C. Hill, colonel B. K. Jamison, and professor Marks of the University were on hand as the representatives of the Edison company, and colonel Jamison was elected a director of the Penn company. It was decided that the council for the company should appear before the law committee of city councils and explain the legal status of that corporation. The Edison company is deeply interested in the subject, because it has spent over $200,000 in laying an iron pipe on top of the Penn company's wooden conduits.

The following is the opinion of city solicitor Warwick, referred to above :

I. Have the councils of the city of Philadelphia the power and legal right to grant to a corporation not incorporated under the laws of the state of Pennsylvania, or to a company, a firm or an individual, permission to lay, construct or maintain a line or lines of telegraph, telephone, electric light wires, electrical conductors, conduits, cables, manholes, pneumatic tubes or steam conductors under the streets or highways of the city of Philadelphia ?

To this I reply as follows: The streets of Philadelphia are under the control of the commonwealth. Any person or corporation claiming a right to occupy and use the streets of Philadelphia for the purposes and in the manner indicated in your question must show authority from the commonwealth. Unless this authority is shown, councils have no power nor legal right to grant permission to such individual or corporation to tear up the streets and lay down lines of telegraph, telephone or electric light wires, or perform any work contemplated in your question.

II. Have the councils of the city of Philadelphia the power and legal right to grant to a corporation not incorporated under the laws of the state of Pennsylvania, or to a company, a firm or an individual, permission to erect, construct or maintain a line or lines of telegraph, telephone, electric wires or poles upon the streets or highways of the city of Philadelphia ?

In answer to this inquiry I desire to say there may be some doubt in relation to the question as to how far a city can prevent the construction of a telegraph line, the same being considered an instrument of commerce (Pensacola Telegraph Company *vs.* Western Union Telegraph Company, 6 Otto, page 8 and others) But so far as the electric light wires or poles are concerned, the individual or corporation proposing to do the work must show authority from the state before permission can be granted by the councils of the city. Foreign corporations may become corporations of this state by complying with the requirements of the act of June 9, 1888.

III. Is there any act of the legislature of the state of Pennsylvania under which a charter can legally be obtained granting to a corporation so incorporated the right to lay, construct or maintain, subject to the consent of the councils of the city of Philadelphia, a line or lines of electrical conductors, conduits, cables, wires or tubes under the streets or highways of the city of Philadelphia, for the purpose of furnishing electric light or power to the public ?

In answer to this I would say that there is authority under sections 2 and 34 of the act of April 29, 1874, to obtain a charter for the purpose of furnishing electric light or power to the public by laying conduits, wires, etc., under the streets of the city, subject, of course, to the consent of councils.

The Penn Electric Light Co., which has been the subject of so much comment in city councils by reason of the city solicitor's opinion relative to the alleged legality of the company's franchise in this city, has a remarkable history. Its projectors have reaped a rich harvest off the public, and they have pocketed not less than $200,000. It has obtained from city councils franchises valued at $5,000,000. Its officers include such well-known persons as Messrs. James McManes and David H. Lane. The company has practical control of the streets of the city.

PHILADELPHIA, Dec. 18, 1887.

BOSTON.

Electric Lighting Notes.—Curious Result from Leaking Gas Mains.—Appeal of the Western Union Telegraph Co. against Taxes imposed by the Commonwealth.—The Boston Electric Club.—The American Bell Telephone Co.'s Output.—Report of the Erie Telephone Co.—The American Telephone & Telegraph Co.—Effectiveness of Safety Guards for Electric Wires.—Electric Street-Railway Notes.

THE stockholders of the Cambridge Electric Light Co, have voted to authorize the issue of $50,000 in bonds to run for five years, with interest at 6 per cent., payable semi-annually. It was voted that $30,000 of the amount be offered to the present stockholders. The meeting also authorized the directors to purchase a suitable site for a new location for the company's plant, owing to the settling of the foundation of the machinery where at present located.

One of the superintendents of the Boston Gas Light Co., while crossing Park square just as the day's business was beginning, on a recent morning, noticed a large sheet of flame coming from the top of the electric light post in the square. He at once had the gas shut off from that section, and an investigation showed that the large main of the Bay State Gas Co. was resting on a four-inch pipe of the old company, and the weight of the main had forced the pipe out of place and caused a bad leak. The gas, on escaping, had followed the line of the pipe to the electric light post—which stands where a lamp post formerly stood—and as the post is hollow, the gas rushed up through it and was ignited by the electric light. It is said that when the flame was discovered it was two feet wide and at least three feet high. The electric light fixtures were destroyed.

It is probable that by Jan. 1 the Westinghouse company will have its electric incandescent lights—1,200 or 1,300 of them—in operation in the Hoosac tunnel. Experiments have been made with satisfactory results over a half mile of the four miles traversed. The power will be furnished by the Fitchburg Railroad Co., either from the water-mills of the Deerfield river that were in use in constructing the tunnel, or by steam. The proposal to light the tunnel involves several novel problems in electrical engineering. Preliminary experiments made last summer showed that the gas and smoke exerted a powerful corrosive effect on the common electrical appliances. Chemical action, as well as perpetual dampness, has therefore to be contended against. The metal sockets usually employed with incandescent burners will not answer at all, and some other material must be employed. Extreme pains will also have to be taken with the connections between the main wires and those leading to the lamps.

Consolidation seems to be the order of the day in all the larger branches of business. The American Electric Manufacturing Co., of New York, has been in consultation with the Electrical Development and Manufacturing Co., of this city, and an arrangement was arrived at by which the entire factory, property and patents belonging to the Electrical Development company will be absorbed by the American company for stock in the latter company.

At a meeting of the Boston Electric Club last evening at its rooms, No. 66 Boylston street, the following-named officers were chosen:

President, P. H. Alexander; vice-presidents, William J. Denver, Suel Smith, E. Wilbur Rice, Jr., Frank Fuller; treasurer, F. J. Boynton; secretary, Robert F. Ross; historian, Allan V. Garratt; executive committee, Frank Ridlon, A. H. Chapman, C. M. Ransom, H. B. Cram, H. J. Pettengill, Edward Blake, Leopold Schlegelmilch, William Brophy, A. L. Rohrer, George W. Adams, Henry B. Lytle, J. T. Moriarty, S. E. Barton, W. I. Barker, Geo. W. Davenport, H. H. Eustis, H. N. Sweet, E. L. Caldwell. F. E. Clark, J. R. Lovejoy.

The annual dinner of the club will take place on Déc. 17th. On Monday evening, Dec. 19, Professor A. E. Dolbear will lecture before the club.

The output of telephones by the American Bell company for the month ended Nov. 20, and for the fiscal year to date, is stated as follows:

November—	1887.	1886.	Increase.
Gross output	4,330	3,340	990
Instruments returned	2,667	1,825	842
Net output	1,663	1,515	148
Dec. 21st to Nov. 20th—			
Gross output	48,670	38,360	10,310
Instruments returned	24,695	18,238	6,457
Net output	23,975	20,122	3,853

The Erie Telephone Co.'s earnings for October are reported, and maintain the substantial improvement heretofore shown. Full figures follow:

October—	1887.	1886.	Increase.
Gross earnings	$53,831	$46,015	$7,816
Gross expenses	32,284	32,132	152
Net earnings	$21,547	$13,883	$7,664
Construction	6,464	2,975	3,489
Surplus	$15,083	$10,908	$4,175
April 1st to Oct. 31st—	1887.	1886.	Increase.
Gross earnings	$354,041	$310,400	$43,641
Gross expenses	230,966	207,168	23,798
Net earnings	$123,075	$103,232	$19,843
Construction	27,470	17,232	10,238
Surplus	$95,605	$86,000	$9,605
Subscribers added—	1887.	1886.	Increase.
October	62	53	9
April 1st to Oct. 31st	639	407	232
Connected Nov. 1st	10,361	9,331	1,030

The American Telephone and Telegraph Co., that branch of the American Bell Telephone Co. which operates long-distance lines, will very soon be in condition to transact Eastern business. They have taken elegant offices at 53 Devonshire street, basement, which are in charge of Mr. Lewis, who has for an assistant Mr. J. H. Jefferson, late an employé in the American Bell general office.

The utility of safety-guards for electric wires received a demonstration recently in South Boston. A telephone line with six subscribers thereon—three of the six being provided with the Farnham safety wax-guards—was crossed with an electric light wire; the three without the guards were burned out. The absolute necessity of providing means of salvation is apparent.

On the 5th inst. another electric street car invaded the crowded streets of Boston, passing through the most busy part of Washington street just at the noon hour. The car was an old one of the Cambridge railroad, fitted up by the Weston Electric Light Co., under the immediate supervision of Col. C. H. Hewins, the company's general superintendent. The experiments which finally resulted in the trip of yesterday began as long ago as last March, when Col. Hewins obtained the use of the car. It was not until about three months had elapsed that the car made its appearance upon the streets, and from that time to this it has run over about all the routes of the Cambridge railroad. It derives its power from Julien storage batteries, the cells, 120 in number at present, occupying the spaces beneath the seats. At first there were only 104 cells, but when the West End's Sprague motor car made its appearance, the additional cells were put in to place it upon equal footing with the Sprague motor, in order to allow proper comparison to be made. The motor on this car is placed beneath the centre, and the power is transferred to the wheels by means of 10 wire belts running from the motor to a pulley on the axle. There is a mechanical arrangement which reduces the speed of the wheels very materially from that of the dynamo. The mode of controlling the movements of the car is by the use of a horizontal wheel, similar to the brake wheels on passenger cars. This wheel tops a stout rod on the car platform, so arranged that, at a moment's notice, it can be transferred to the other platform, leaving one platform entirely clear all the time. There is not even the rattling noise of the ordinary horse cars. Two sets of batteries will be required to operate a car each day, ten hours being required to charge each. The number of miles actually to be run by them, regardless of stops, has not yet been determined by Col. Hewins. Col. Hewins states that, from the first trip made by the car until the present time, it has always returned to its stable without the assistance of horses, and during that time it has climbed the worst grades on the Cambridge road, even accomplishing the very steep ascent of the Newton hill, rendered more difficult as it is by a considerable curve.

The trip was from Harvard square, up Cambridge street hill, through Court street, Cornhill, Washington street, Temple place, Tremont and Boylston streets, Park square, Church, Boylston, Charles and Cambridge streets, back to Harvard square. Cambridge hill was climbed easily, but the mud and slime on Washington street was too much for the car, until some sand was procured and placed upon the rails, when the car moved quietly onward.

The progress of the car was watched with interest by thousands of people upon the streets. It is the intention to soon place it in the regular traffic between Boston and Harvard square, and thus it will be given an opportunity of practically demonstrating its ability and its reliability.

It is thought that work on the Quincy street railway will be begun early next spring. The motive power, which will be electricity, will be furnished by dynamos run by two 50 h. p. engines. The current will be distributed over the route by an overhead copper wire. This wire will be about a quarter of an inch in diameter, and strung on arms projecting over the track, the arms being fastened to poles. The electricity is conveyed to the motor, which is in the front end of the car, by a wire, which is attached to two grooved composition wheels which run overhead on the main wire at the same speed the car travels over the track. The cars will look like the ordinary horse-cars, and will be lighted by electricity. It is expected that a speed of 15 miles an hour can be attained.

BOSTON, Dec. 16, 1887.

CHICAGO.

Mr. C. N. Fay leaves the Chicago Telephone Co. and accepts the Presidency of the Gas Trust.—Mr. B. E. Sunny also leaves the same Telephone Co. to become President of the Chicago Arc Light Co.—Mr. Geo. L. Phillips to be President and General Manager of the Chicago Telephone Co.; That Company's Franchise.—The City Council seeks State Intervention Against the Gas Trust.—A Fuel Gas Co. to Compete with the Gas Trust, using Incandescent Gas Burners: The Welsbach Incandescent Burner Attracting Attention.—Delay in Constructing the New Edison Light Station. The City Electric Light Plant Nearly Ready for Use.—The New Building of the Chicago Telephone Co.—The Chicago Arc Light and Power Co. to Consolidate Outlying Stations at one Point.—Some Features of the New Station.—The Westinghouse Electric Light Plant at Denver, Col.—The United States Electric Lighting Co. Installing Alternate Current Plants in the West.—Mr. J. Humbird Appointed Selling Agent by the Westinghouse Electric Co.—An Old St. Louis Gas Company to Take Up Electric Lighting. A Combination of Manufacturers to Defend the suit of the Brush Electric Co. against the Faraday Carbon Co., for infringement of patent on copper-plated Carbons; Other Litigation.—Mr. G. S. Ladd and Mr. J. C. Henderson, of San Francisco, in Chicago.—The Large Eastern Interests Represented by Them on the Pacific Coast.—Mr. K. Sawai, of Japan, Studying Practical Electrical Engineering in Chicago.—The Recent Rise in Price of Copper and Other Metals.—The Chicago Electric Club.

NO occurrences in electrical business this month have attracted more attention here than the resignation of Mr. C. N. Fay as general manager of the Chicago Telephone Co., to accept the position of president of the Gas Trust, at a salary, it is stated, of $20,000 per annum, and the resignation of Mr. B. E. Sunny as superintendent of the Chicago Telephone Co. to accept the presidency of the Chicago Arc Light and Power Co.

As president of the Gas Trust, which is very unpopular just now in Chicago, Mr. Fay will have abundant opportunity to use the ability which has won the position for him.

The Chicago Arc Light and Power Co. is practically a branch of the Gas Trust, the same stockholders controlling both organizations. Mr. Sunny's promotion is a source of gratification to his many friends. But it will be difficult to find a man who will fill so acceptably and so ably as Mr. Sunny the position which he leaves in the Chicago Telephone Co. The resignation of both gentlemen take effect January 1 next, and it is understood that Mr. George L. Phillips, now president of the Central Union Telephone Co., will become president and general manager of the Chicago Telephone Co.

The question of the validity of the franchise under which the Chicago Telephone Co. has been and is carrying on business was referred to the corporation counsel, Judge Green, who has rendered an opinion, in which he says that the Bell Telephone Co., to whom the original franchise was granted, had no power or authority under the terms of the franchise to assign it to the Chicago Telephone Co. The franchise is therefore void. But the city has done business with the present company in accordance with the terms and provisions of this franchise, and Judge Green is therefore of opinion that this fact may be regarded as constructive admission on the part of the city of the validity of the charter. Nevertheless, as these business arrangements have been almost entirely with the executive officers of the city, a doubt is expressed as to their action being in any way binding on the city.

The city council, finding the legal position of the Gas Trust strong enough to resist the attack of the municipal government, has called in the assistance of the state by requesting the attorney-general to bring *quo warranto* proceedings against the gas companies composing the Trust to compel a forfeiture of their charters. The attorney-general has signified his intention to commence such proceedings forthwith.

Another opposition to the Gas Trust has appeared in the shape of a company which proposes to use fuel gas with the Fahanjelm incandescent gas burner. The Welsbach incandescent gas burner also is attracting the attention of some capitalists, and will very likely come into extensive use unless the frailty of the mantle of refractory earthy material, which is the distinguishing feature of this burner, should prove here, as it has proved in some instances in Europe, such as to render it unfit for practical service.

The progress of the work of constructing the Edison electric light station has been delayed by various causes, one of which has been the changes in the details of the building which is in course of construction for this plant. These changes are found necessary to meet the requirements of the installation, which are new in many respects. The delay on the part of the manufacturers of iron beams also holds back the work, so that it now seems impossible that the plant should be in operation by the 1st of February.

The contractors for the construction of the city plant for lighting the bridges and viaducts say that their lights will be turned on by January 1st.

The handsome building of the Chicago Telephone Company is nearly completed. At least the walls are up and the roof is on, and the work of finishing the interior is progressing rapidly. The building will be ready for occupancy and the consolidated central office, with a multiple switch-board for 3,000 subscribers, will be ready for service by May 1st, 1888.

The Chicago Arc Light and Power Co. is making ready to move the dynamos, which now occupy various stations around town, into the grand central station at 76 Market street, where to begin with there will be 32 dynamos, of capacities ranging from 25 to 50 lights, all in operation. The Western Electric Co. is building the large switch-board for this station, after plans prepared by Messrs. Cushing and Brown, of the Chicago Arc Light and Power Co. It will have 160 spring jacks, with two auxiliary sockets to each jack, and all metal parts will be protected so as to avoid all danger to the attendant. There will be used in running the circuits from the switch-board to the sidewalk, where the lines enter the conduits, 15,000 feet of okonite wire.

The large Westinghouse plant of the Colorado Electric Co., in Denver, was recently started successfully. There is already a demand for more lights than the entire present capacity of the plant.

Notwithstanding the fact that the Westinghouse Electric Co.

has brought suit against the United States Electric Lighting Co. for alleged infringements of patents, the latter company is installing alternate current plants in various places in the west.

Mr. James Humbird, formerly of the firm of Humbird & Gorton, western agents of the Edison Electric Light Co., has been engaged by the Westinghouse Electric Co. as their general selling agent.

The old, rich and conservative Laclede Gas Co., of St. Louis, has decided to embark in the electric lighting business. Following is the statement of captain John P. Keiser, president of the company:

"We have been forced to do this by the increasing popularity of electricity as an illuminating means. A large number of our best patrons have discarded gas and substituted electricity for it, and in order to keep up with the times we have had to take measures to provide for the people who want light the kind of light that they prefer. Electricity is rapidly coming to be the light for streets. Detroit is lighted by electricity, so is New Orleans and so is Terre Haute. We expect that our electricity will be demanded most by business houses, and for lighting the streets. There will be little need of it in residences. We are now lighting 4,000 city lamps, and receiving $37 a year for each. When our contract expires we expect to have to bid against close competition of all kinds, and we will offer the city electricity, if it will have it, for all its streets. The charter of our company which allows us to use electricity as well as gas, also permits us to furnish the electric light to consumers in any part of the city. What the difference between the cost of street lighting by electricity and by gas will be, I can't say, nor am I prepared to state what system of electric lighting is likely to find most favor with the directory. We intend to get what we think is the best system, without regard to its cost. Then the company will be in the position it desires, prepared to compete with either gas or electric light companies for private or municipal business. This is about as far as we have got with our plans now."

In this movement the Laclede Gas Co. is falling into line with the very considerable number of gas companies in all parts of the country that are either operating or erecting electric light plants. The number of such companies is increasing very rapidly in all directions.

The suit brought by the Brush Electric Co. against the Faraday Carbon Co., for alleged infringement of the Brush patent on copper-plated carbons, will be defended by a combination of the manufacturers of carbons. Mr. Fish, of Boston, has been engaged to conduct the defense, so if the Brush Electric Co. expected to obtain a judgment by default in this case it will be disappointed.

The case of the Brush Electric Co. against the Fort Wayne Jenney Electric Light Co. was tried this month at Indianapolis. No decision has been rendered in this case. The patent in question is the one on the differential magnet.

Mr. G. S. Ladd and Mr. J. C. Henderson, respectively president and general manager of the Electrical Development Co., and of the Pacific Electrical Storage Co., spent some days in Chicago recently. The Electrical Development Co. is the agent on the Pacific coast of the Edison Electric Light Co. and the Western Electric Co. The Pacific Electrical Storage Co., which is a licensee of the Electrical Accumulator Co., of New York, is preparing to build a factory in San Francisco for the manufacture of accumulators, as the expense of transportation is so great as to make it inexpedient to have them carried from New York.

An interested and interesting attendant of the meetings of the Chicago Electric Club of late has been Mr. K. Sawai, now engaged in studying practical electricity and electrical apparatus in this country, after his theoretical training in the Japanese university, of which he is a graduate. Mr. Sawai shows much zeal in his pursuit of knowledge. He secured permission of the Western Electric Co. to enter their shops as a workman, and he is always at his post ready to perform any duty assigned to him. He intends to remain in this country for a year or two and then to spend some time in Europe before returning to Japan.

The recent large advance in the prices of metals, especially copper, zinc and tin, is watched with much interest by every one engaged in the manufacture or use of electrical apparatus. The feeling here is, that while prices, particularly of copper, may have been too low for some time back, the present enormous advance is going too far the other way; that present prices may last three months or a little more, but that the tendency will soon be downward, and in the spring will reach a more reasonable figure, and one that will be more satisfactory to the electrical interests of the country.

The Chicago Electric Club has held its usual two meetings this month. At the first Mr. C. K. Giles read a paper on magnetism in watches. At the last meeting a paper was read by George H. Bliss on automatic temperature regulation. The club is making arrangements for a banquet on the evening of January 7th, and as an evidence of the prosperity and stability of the club, which has now a membership of nearly two hundred, billiard tables will soon be added to the attractions of the club rooms.

CHICAGO, Dec. 24, 1887.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, *115 Nassau Street, New York city.*

MR. KINTNER'S EQUATION FOR A TELEPHONE CURRENT.

[83.]—In THE ELECTRICAL ENGINEER for December, Mr. C. J. Kintner gives a diagram and this equation for the currents produced by "a pure musical tone entirely free from harmonics," $c = \frac{vt}{d^2}$. If he is going to make further use of this equation, or if the further discussion has any connection with it, I should like to have some light upon it.

Mr. Kintner says "v may be assumed constant for any interval of time, since the power due to this particular sound-wave is a constant, so that the velocity tends to be of a constantly accelerated nature, but is, in fact, opposed by a constantly increasing power—the elastic stress of the diaphragm." If a pure musical tone without harmonics is maintained in a column of air resting on a diaphragm, the energy transmitted to the plate is not constant, even during the interval of the impinging of a single condensation. It is true that the energy of the molecules of each of the successive cross-sections is constant. But this constant energy is made up of two parts—a kinetic part due to velocity of the particles, and a potential part due to their displacement from equilibrium positions. Only one of these, the kinetic part, has any effect on the diaphragm. The action of the wave on the diaphragm must be of variable "power," instead of constant. But even if it were constant, can Mr. Kintner show that the elastic stress of a plate, clamped around its edges and under uniformly distributed pressure over the central region, increases in such a way that the velocities of its parts are constant under a constant accelerating force? Again, has he taken into account all the forces acting to give the diaphragm velocity? He mentions only wave energy and elastic stress. Does not the change of magnetic induction and field intensity, as *d* changes, affect the velocity?

"There is generated during the advance of the diaphragm a plus current of constantly increasing volume, until the value of *d* has diminished sufficiently to change its volume." I do not understand how diminishing the distance of the diaphragm is to decrease the volume of the current, especially with v constant. Is not the volume of current due directly to rate of change of magnetic force within the coil? And is not this rate of change of magnetic force some function of (*a*) the velocity of the diaphragm and (*b*) the magnetic field? Is not the diaphragm velocity a function of variable wave-energy, variable elastic stress, variable magnetic stress again varied by variation of current, and variable time? Is not the magnetic field, in form and intensity, some function of the physical conditions of the core and diaphragm, the variable current strength, and the variable distance?

I would offer the following, in place of Mr. Kintner's first equation:

$$c = \varphi\,(\text{velocity, field,})$$
$$= \varphi \left\{ \begin{array}{lll} \text{variable wave energy,} & \text{variable current,} & \\ \text{" elastic stress,} & \text{" distance,} & \\ \text{" magnetic "} & \text{etc.} & \\ \text{" time,} & & \end{array} \right\}$$

But I have no diagram of the volume of currents to offer until I have time to investigate some, and calculate others, of the final variables. I. THORNTON OSMOND.

State College, Pa., Dec. 9, 1887.

THE WESTINGHOUSE ALTERNATING SYSTEM.

[84.]—All the explanations heretofore published of the Westinghouse dynamo have been deceiving as to the number of reversals the machine gives, and I see that Mr. Addenbrooke, in an article in your paper for December, has gotten a false impression when he comments on the number of reversals being unnecessarily high.

The 650 and 1,300 light machines have a speed of 1,650 revolutions, but they have only 10 field magnets instead of 16, as I have seen it stated in a number of electrical papers. This would give 16,500 alternative 33,000 reversals per minute, instead of 40,800, as Mr. Addenbrooke is led to believe. AN OBSERVER.

Pittsburgh, Pa., Dec. 10, 1887.

ELECTRICAL NEWS AND NOTES.

THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

SPECIAL MEETINGS—DECEMBER, 1887.

MEETING OF DECEMBER 6.

The President, Mr. T. Commerford Martin called the meeting to order at 8 o'clock P. M. and said: The subject which we have before us this evening is one of the first importance. I therefore have much pleasure in asking Mr. William Stanley, Jr., the electrician of the Westinghouse Electric Co. to read us his paper on the "Phenomena of Retardation in the Induction Coil."

Mr. Stanley then read his paper. (See page 5.)

DISCUSSION.

Mr. Townsend Wolcott—I would like to ask Mr. Stanley if he has ever observed an effect in reversing the magnetism of the cores other than that of the Foucault currents, that is, a sort of magnetic friction; the mere reversal of polarity, independent of any induced current, producing an amount of energy. I do not know how much it is. I know that some years ago a French physicist experimented with alternating currents, using a copper core in one case and an iron core in another. Had the heating effect been due to the Foucault currents, the copper would have become much hotter than the iron, while in fact they did not get hot at all, while the iron became hot; so there was an effect due to the simple change of polarity—a sort of friction—it is analogous to friction. I would like to know how much effect that has in practice on the alternating systems.

Mr. Stanley—In measuring the loss in an induction coil we have found a very slight unaccountable waste, so slight, though, as to be almost immeasurable. It depends somewhat on the number of alternations that are driven through the coil. With about sixteen thousand alternations a minute the temperature of the coil, if it were placed in a calorimeter, would be indicated. The temperature of the calorimeter would indicate very nearly the amount of energy which was due to C^2 R, or the heating of the conductor itself. The iron of the core of the converter or the induction coil remains at a very low temperature indeed. Of course there is a considerable radiation while in the air. Mr. Shallenberger, in Pittsburgh, has made several careful measurements, and we are enabled to find that there is hardly any perceptible loss from magnetic friction. I can well say that with a very high degree of magnetization where the core was of a limited area in proportion to the number of ampere turns surrounding it, that there might be a considerable waste due to magnetic friction or magnetic saturation, and with the induction coils as made for the distribution of electricity for lighting purposes this is very small indeed. I cannot tell you its extent, but it is very small.

Mr. Howson called attention to the fact that a distinction had to be made between the true alternating current and the reversed or interrupted direct current.

Mr. Stanley remarked that for the purpose of distribution by means of transformers the interrupted or reversed direct current was of very little value, and said further: With your permission, I will endeavor to sift out this subject a little bit more. As I understand it, the effect of joining the magnetic circuit around the primary and secondary induction coil is practically to reduce the wire, if I remember correctly, to about one-sixth. In experimenting with coils, to begin with, I took Faraday's ring and wound a coil on either side. The best coil I have ever seen consisted of a bundle of perfectly straight wires on which was threaded a lot of iron washers. This has the highest counter induction per unit of length of any coil I have ever seen. In the Westinghouse company's system we get about two volts per foot of wire. This coil gave, if I remember correctly, about a volt to four inches. But it was impracticable to construct, as you could not make them fast enough. As I understand it the curves of electromotive force induced from an alternating current are these. A, B, C, D, E (see figure 5, p. 7), is a complete period of the curve of the primary or applied electromotive force. Now the induced electromotive force will be maximum at the time when the inductive effect of this primary current is a maximum; and the inductive effect of the primary current is a maximum when it changes from zero to any larger value. Consequently, the electromotive force of the induced current shown in the lower curve, figure 5, will be a maximum at this time; and it will be a minimum when the inductive effect of the primary is a maximum, and that will be when the rate of change of the primary is the least, viz., at the crest of the primary wave B and D, we find that the same values of applied and counter electromotive force are just one-fourth of the whole period of phase of the current. That is with an alternating current. In the direct current we never can have as great an electromotive force induced in the secondary circuit because our primary circuit never passes the zero line. The curve of induced electromotive force in the case of a broken, direct or interrupted direct current I think is this (figure 1). As will be seen, the induced current will be of negative sign, while the positive current is going to maximum; and the induced current will be of positive sign, while the applied current is falling from the maximum.

Perhaps it might be interesting to illustrate the applications of induction coils for covering long-distance distribution. It is well known that the cost of a conductor varies inversely as the square of the electromotive force. The cost of the conductor for transmitting a given amount of energy will be, for 100 volts E. M. F., we will say, x dollars, while for a 200 volts pressure the cost will be $\frac{x}{4}$ dollars. Therefore, the economy of the alternating system over others is directly as the square of the ratios of their electromotive forces. But in order to cover enormous distances and to make the system as broad as possible, I devised another plan which may or may not be new. We are to apply it in Berkshire county, Mass., to distribute from a station over six miles of territory with a loss of two per cent. We have 100 h. p. to distribute, and the potential of distribution is to be 4,000 volts. Our alternating current dynamo is of 1,000 volts. In order to get the electromotive force up to 4,000 volts we simply wind one coil of wire and attach our dynamo to intermediate terminals of that wire, distant apart one-fourth of the entire length (as shown in figure 2). That is, the length included between the terminals is one-fourth of the whole length of wires wound on the coil. There is no secondary circuit whatever. Of course, there is an induced electromotive force upon every turn of wire on that core of so many volts per turn. We apply our electromotive force of 1,000 volts at those points in order to get 4,000 volts between the outside terminals. When we carry our current at this enormous potential over to the place where we wish to distribute we simply attach another self-induction coil similar to the first. On one-fourth of its entire length we tap out another circuit. That reduces the potential from 4,000 volts to 1,000 volts again. The maximum efficiency of an auto-converter, or converter of one

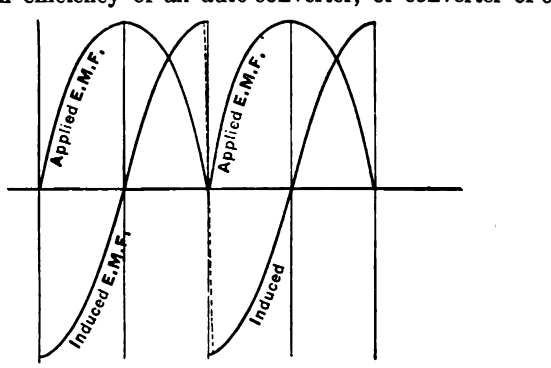


FIGURE 1.

coil evidently is found in the case where the ratio of reduction is from one to two, or two to one. If you have it in the ratio of one to four, or one to six, the saving is not nearly as great.

Mr. Prescott—I visited the station in the Berkshire hills a few days ago that Mr. Stanley speaks about, and I noticed that they had for the generators one omnibus wire running around the station such as are used in the Edison station. But this omnibus wire was split in two, and each generator worked into its own circuit. I asked the attendant why the omnibus wire was not connected across, and he said that if they connected it across they were likely to burn out their armatures. I would like to ask Mr. Stanley if that is so?

Mr. Stanley—That is so, through an oversight in the construction of the dynamos in the early stage of the business. We all have to learn some things; and the reason why it has been difficult to multiple-arc alternating dynamos is, that the phases have not been exactly the same. We make our dynamo pole-pieces of cast iron. Those cast iron pole-pieces did not measure to a thousandth of an inch the same width, and consequently the two phases of current, which ought to have coincided, did not coincide exactly, simply because of faulty construction. By tooling off and cutting the width of the pole-pieces to an exact measurement, there is not the slightest difficulty in multiple-arcing two, three or four alternating dynamos. I think a new feature in alternating currents, perhaps not well known to every one here, is the remarkable self-regulation of the alternating current machine. I cannot speak of it fully, because I have had very little to do with it. Another man is responsible for the beautiful work he has succeeded in getting. In Pittsburgh, a few days ago, I saw a 2,500-light dynamo run by a 250 h. p. engine, and 2,150 lights thrown by a single switch. The rise in electromotive force was one volt. I submit that in the present state of the art, it is impossible to construct a direct current machine which shall have anything like the self-regulation these alternating machines exhibit. The resistance at the commutator of a direct current machine would cause a greater variation of potential than was manifested in this machine I speak of. In the induction system we start out with an alternating current machine, in which we pretend to have at least a maximum loss of two volts in electromo-

tive force in the dynamo with the proper regulation necessary to any machine. Towns are wired, at least I know of two pole lines which are wired, for one per cent. loss of electromotive force, distributing electricity generally over an area of about a mile radius. The actual loss in the mains is one per cent. In the induction coil, at full load, there is another loss of two per cent.

Mr. Mailloux—I was expecting that somebody would refer to one of the features mentioned by Mr. Stanley this evening, which is to me one of the most interesting, from the theoretical as well as from the practical standpoint, inasmuch as it leads to a scope of applications. It is that system in which four lamps, A, B, C, D, were connected across the terminals of a constant potential alternating circuit; and in which the difference of potential for a particular lamp cut out was taken up by the self-induction coil (see figures 9 and 10, p. 8). Now I would like to ask Mr. Stanley whether the object of using that induction coil was merely to balance the other lamps, or whether it was expected that any energy would be saved by its use; in other words, whether the two lamps running with the circuit continued through the self-induction coil would require less current than would the four lamps.

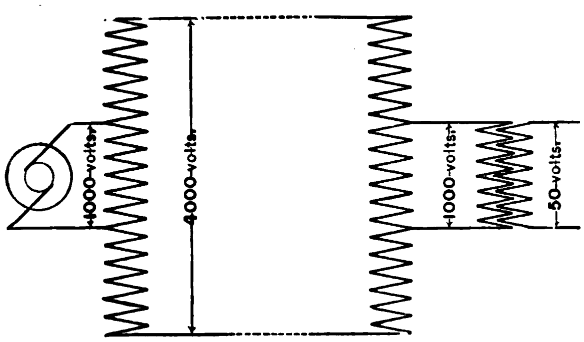

FIGURE 2.

Mr. Stanley—The connection of the lamps in series in that way was for a street-lighting system. In order to distribute lamps economically for street lighting purposes the plan adopted by Mr. Shallenberger was brought out. The shunted coil on the extinguishment of any one lamp prevents the rest of the lamps going out. For instance, there would be 20 lamps attached to a 1,000-volt circuit, each lamp of 50 volts. Now all those 20 lamps may go out, or 19 go out and the remaining lamp would be at approximate candle-power; and yet the sum of the electromotive forces, measured by a volt meter around the lamps and coils, is far in excess of the electromotive force that is applied to the outside terminals of the series

For instance (referring to figures 9 and 10, p. 8), there are four lamps connected in series. There was a lamp connected at *a*. That lamp is extinguished and in place of it there is a self-induction coil, *e*. This series is connected to a circuit whose voltage is 200 volts; a volt meter connected to each one of these lamps will show for the lamps *b*, *c*, *d*, 50 volts each, and for the self-induction coil, 100 volts. Now the sum of the interior electromotive forces here is 250 volts. The same volt meter will show an electromotive force of 200 volts on the outside terminals. That is, the sum of the interior electromotive forces is greater than the applied electromotive force. I think that can only be explained by the retardation of the current producing the average electromotive force.

Mr. Prescott—In regard to the point that Mr. Stanley kindly replied to a moment ago, I would say that it is of course well understood that if the time phases of any number of alternating current machines are identical there is nothing to prevent their being worked in a multiple arc. Now the question to my mind was whether there is any practical difficulty in getting those time phases the same. Of course that includes not simply the electrical and mechanical construction of the machine; it requires them to be identical in that respect. Now I have seen only two Westinghouse stations, and in both of them, each dynamo had a separate engine and in both cases the machines supplied separate circuits. Is there any case of any plant now in operation where a number of machines are successfully used in multiple arc?

Mr. Stanley—I think at Denver, Col., a station of 5,000 lights is run with dynamos in multiple arc, although I am not sure. The Pittsburgh station has been run in multiple arc. Our policy is not to run in multiple arc. We prefer not to. There is no choice in the matter excepting only that of simple expediency. We construct the station switch-board so as to connect any circuit leading from the station to any dynamo without causing a flicker in the lights, and thus give the dynamo a definite load that you can read on the amperemeters. That seems to us to be a very satisfactory way to run. As the evening grows later lights are cut off, the circuits are transferred from a number of dynamos to perhaps a smaller number, and eventually down to one dynamo, which runs all night.

The subject of multiple-arcing of the dynamos comes so near the question of running alternate current motors that it is the same question practically, and I feel, perhaps, justified, in explaining a little phenomenon in that. If you take two alternating current dynamos and couple them together, and start them up, one dynamo will fall into synchronism with the other. In order to have an alternating current motor, it is necessary to have a direct current through the field and an alternating current through the armature. In order to get a direct current through the field, you have got to have a commutator, which will produce the field current. This current in the field will rise from zero to a maximum value and fall again to zero value, but the armature currents will be above and below the zero value (as shown in figure 3). Now, notice, that at the time marked by the full vertical lines, there is no current flowing through the field, and there is no current flowing through the armature. If, then, we have an alternating current motor which is running with the exact speed and in conformity with the number of alternations of the dynamo which is applied to it, and have the phases of the two currents in exact synchronism, that is, with equal phases coming together at the same times, we will have absolutely no current in the field while there is no current in the armature of the motor. Now the commutation of the field may be outlined as shown where C C C indicate the commutator segments. There has been, until the motor arrived at synchronism, commutation at different points in the phases as at the dotted vertical lines. But when the motor runs at exactly the same speed as the alternating dynamo, there is no force then at work keeping the motor going. In other words, you can run an alternating current motor up to speed, but the minute it goes into absolute synchronism it will fall off again, and the consequence is that the alternating current motor will see-saw. There will be no power to continue its motion. Its speed will fall, and it will drop down to a lower number of alternations, but will rise up again.

Mr. Prescott—What is the effect if you have just enough work on to keep the speed down?

Mr. Stanley—Then it will never rise to synchronism.

Mr. E. W. Rice, Jr.—I would like to ask Mr. Stanley in reference to his last statement as to the motor, what percentage is the variation in speed?

Mr. Stanley—Of course an alternating current motor in synchronism and kept there, runs at exactly the same speed as the alternating current dynamo does. If the motor is impelled to synchronism and beyond it, it will go to perhaps double the synchronism. If the alternating current machine is run 16,000 alternations per minute, the alternating motor if it goes beyond that number, would never stop until it gets to 32,000 alternations. But the chief difficulty is that it does not develop any counter electromotive force under the conditions described, because it cannot develop a counter potential unless it has at all times a constant field charge. As the current falls to zero, of course, it cannot develop any counter electromotive force at that time. An alternating current motor has no efficiency of any consequence until it arrives at synchronism and becomes practically a dynamo running in opposition to the dynamo applied to it, at which time it has an enormously high efficiency with the most perfect self-regulation.

Mr. Rice—I hardly understand what Mr. Stanley means, in view of some experiments we tried recently. We had a self-exciting dynamo, and ran it in multiple arc with another self-exciting

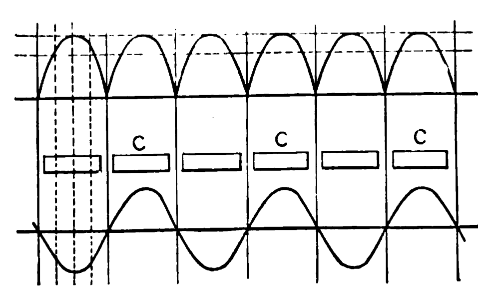

FIGURE 3.

dynamo, and then threw the belt off. The current from the generator proper passed from the armature of the motor. We did not find any variation to speak of, and it ran perfectly in synchronism. It was a generator capable of giving out about 25,000 watts. I then loaded it until the motor was giving out in the neighborhood of 50,000 or 60,000 watts without any change whatever in speed or any tendency to variation.

Mr. Stanley—It has an alternating field in which the magnetization periodically fell to zero. But in the dynamo the gentleman speaks of I understand the magnetization of the field was always the same. Consequently it was a true alternating current motor.

Mr. Rice—I do not see exactly how that meets the question, because the field of the motor was charged by itself, therefore it was falling from zero to zero again.

Mr. Stanley—The field of the motor was charged by a current developed by the motor itself on its own armature.

Mr. Rice—Yes, sir.

Mr. Stanley—And the phase of the current did not coincide with the phase of the applied electromotive force.

Mr. Rice—If I understand you for a certain period of time a motor running is exciting its own field. There was no opposition to the primary current from the generator.

Mr. Stanley—That is true. When the current in the field is zero, and the field charge is zero, then there is no electromotive force producible of course. But if the field charge is constant then it will develop a counter electromotive force and become a true motor.

Mr. Rice—I understand you to say that the field would fall to zero from the self-exciting motor.

The President—I would like to ask Mr. Rice if he is at liberty to give us a little information on the point of synchronism?

Mr. Rice—All that I can say in regard to that is that we have tried multiple-arcing dynamos. We have run dynamos together for a period of twenty hours continuously, and the loads seemed to be very equally divided, when the speed was kept uniform. We have also experimented with motors and found no difficulty in that direction.

I was very much interested in the system which Mr. Stanley attributes to Mr. Shallenberger. I think it is only just to Professor Elihu Thomson to say that that system was patented by him three or four years ago. He used almost identically that same arrangement which consisted of placing a self-inductive coil in place of a lamp, so adjusted that it would take just the current of the lamp. I do not know that that was the first time it was done, but so far as I know it was.

In reference to figure 4 (see p. 7), I do not know that I correctly understand Mr. Stanley's explanation of it. The diagram, I understand Mr. Stanley to say, applied to a coil in which there were iron cores. Is that true?

Mr. Stanley—Yes, sir.

Mr. Rice—And you say that the self-induction follows exactly the primary. Now it seems to me that coils with iron or without iron are the same excepting a difference in degree; there is no difference in kind. In that case it seems to me there would be a slight shifting.

Mr. Stanley—The difference in ratio is only one thirty-thousandth, and it being so small I thought it was not worth while expressing it.

Mr. Wheeler—I would like to ask Mr. Stanley whether there are any losses on the line wire other than that due to resistance—whether there is any current dissipated by retardation, self-induction, or anything of that sort?

Mr. Stanley—I was perhaps the worst frightened of any man who ever stood on solid ground when I read Professor Hughes' lecture on self-induction. But the effect of self-induction which he described, and the measurements on which it was based, were made with a broken direct current. With the system that we use we have been able to find hardly any variation from the true Ohm's law, and all our wiring details are based on the assumption that the resistance is the ohmic resistance of the copper only. In the case where the wire goes around an iron core it is not necessary that there should be a loss of electromotive force. The electromotive force is merely retarded for a moment, and as soon as it has fallen to a value below that of the charged magnetism, the stored electromotive force is all returned to the circuit. I think there is nothing so generally misunderstood as the loss of electromotive force in iron cores.

Mr. Wheeler—It is a case of magnetic storage.

Mr. Mailloux—I do not think Mr. Stanley exactly answered my question, and the remarks made bring us back to it again. The question is whether in that circuit that he speaks of in which an induction coil is substituted for a lamp, whether the loss of energy, in other words, the expenditure of energy, across that line is different in the second case from what it would be before that induction coil had been substituted. If, as Mr. Stanley argues, the effect of self-induction is simply to retard the electromotive force, then evidently we still have electromotive force there, and if it does not absorb electromotive force or cause no loss, then we should take less energy than would be accounted for by that which would be absorbed in the three lamps, plus that absorbed in the ohmic resistance, as he calls it, of the self-induction coil. For we must remember that the amount of energy required at the terminals of the induction coil is not as much as would be represented by C^2R. It is C R, plus a certain quantity which represents the work done in the induction coil in overcoming the counter-electromotive force of the coil. Now, then, it is interesting for us to know whether in that case the expenditure of energy was the same whether the induction coil was on or whether the four lamps were burning at one time. I incline to the opinion that it must have been the same, and that consequently there must have been a certain amount of work which was absorbed and dissipated by the self-induction coil.

Mr. Stanley—The energy on the lamp is exactly the same. If it were not the lamps would grow brighter. The potential on them is constant. The current going through them remains constant or they would not be of the same brilliancy. The self-induction coil does waste some energy, but it has the effect of storing energy for a brief interval of time and then returning it upon the circuit. As to the invention of the self-induction coil for this purpose, I have the very highest regard for Professor Thomson and always had, but if I remember correctly, the patent that Mr. Rice refers to is not for this purpose. It is for cutting in a coil. This is a very different invention. This is a coil always in circuit to do this work, while the coil Professor Thomson devised is cut into the circuit.

Mr Mailloux—I would like to state then that my conviction appears to be upheld by Mr. Stanley, that, the energy being the same, this induction coil represents nothing more than resistance. It takes up a certain amount of energy which a certain idle resistance would clearly absorb. If we were to replace that self-induction coil by another one having no self-induction, but a larger resistance, so that the circuit going into that resistance would absorb the same number of watts, then we would evidently have the same energy absorbed as we have by that induction coil. So that I do not see the induction coil in question does anything more than to replace a lamp that is put into that circuit. The case is exactly analogous to that of an electric motor that would be placed in circuit. The amount of energy absorbed by an electric motor is the difference of potential at its terminals.

Mr. Wetzler—It occurs to me that perhaps this phenomenon might be due to an error, or a peculiarity, of the measuring instrument employed. Mr. Stanley said that he employed a Cardew voltmeter. I would like to know whether he ever applied the electro-dynamometer for that purpose.

Mr. Stanley—The electro-dynamometer is a very unfortunate instrument to use with an alternating current, as its reading is changed by a slight fluctuation in the alternations. The Cardew voltmeter, which is dependent on the amount of heat produced, is entirely independent of the alternations. Perhaps I can explain that. The coil is acting exactly as a dynamo would act in series and it chokes down the current in direct proportion as the resistance in this part of the circuit is raised. The average electromotive force at the terminals of the coil, however, is greater than would seem to be warranted by Ohm's law.

Mr. Howell—Mr. Stanley said that inasmuch as the current was constant (as shown by the lamps) that is, the current in three lamps was the same as the current in four and that the electromotive force acting on the circuit was also constant, that the energy was constant in the circuit. I would infer then that C E is the measure of energy in the alternating current. Is that a correct conclusion?

Mr. Stanley—No, sir; that was a slip of the tongue perhaps on my part; but it is a most unreliable quantity. The energy of three is the same as the energy on the three lamps before. I think in reality there is very little waste of energy, But there is an apparent amount of energy wasted there—that is C E of coil. This is apparently as much as the energy expended on the lamp.

Mr. Howell—I think that that diagram is a very good illustration of the fact that C E is not a measure of the energy in alternating circuit, because you have only a value for C there, and the value of the energy in that circuit would be $C \times 200$. Now that is the sum of the energies in three lamps and the coil, and in each lamp it would be $C \times 50$, and in the other it would be $C \times 100$; so that the sum of these energies is not the same as the sum of the whole circuit computed the other way, which shows C E is not the measure of the energy in the circuit.

I would like Mr. Stanley to demonstrate why the current in the secondary increases, or why an increase of current in the secondary increases the current in the primary.

Mr. Stanley—I think that it is very easy to understand from the diagram (see figure 7, p. 8) of the counter-electromotive force, providing no current is flowing through the coil. The secondary electromotive force will of itself induce another electromotive force, and so we might go on inducing forever electromotive force. We cannot merely transform energy once; we can transform it a thousand times. Now the secondary electromotive force will develop a counter-electromotive force on the primary circuit, and that will be still one-quarter of a period later. Notice that I have drawn these curves directly opposite. It exactly opposes the primary electromotive force at the same instant of time. Now, when the current is abstracted from the coil, this is no longer the position of the secondary electromotive force; it is shifted on. Consequently, the counter-electromotive force no longer opposes the primary electromotive force at the maximum time of the primary electromotive force, and consequently its value as a counter or opposing E. M. F. is very much lessened. You have asked me a difficult question.

Mr. Wheeler—I would like to return to the three lamps in the induction coil, because I want to ask this question. Mr. Stanley stated, if connections were made between the main conductors we would have 200 volts; in figure 5, the terminals of coil *e* would measure 100 volts, and *f g h* would measure 50 volts, making a total of 250. Now I would like to ask Mr. Stanley what he would get if he measured the potential between the + conductor and the right-hand terminal of lamp *b*.

Mr. Stanley—I have never tried it.

Dr. Vander Weyde, at the close of the discussion described some of his early experiments with the induction coil, and exhibited a number of early models, in which attempts are made to completely close the magnetic circuit of the coil. One of these, figure 8, was made with long wires for the core, which wires were then bent over the sides and completely inclosed the coil.

MEETING OF DECEMBER 20.

Mr. T. C. Martin, President, said—I am very glad that, in spite of the inclemency of the weather, we have so large an attendance this evening of those who are genuinely interested in the question of patent reform. The subject of a revision of the patent law will be brought before us this evening by Mr. Arthur Steuart, who is the general legal counsel of the National Electric Light Association. The subject is one, I may say, that lies well within the province of the Institute of Electrical Engineers. It has been brought before us on various occasions, and it is somewhat interesting to recall that at our very first meeting, held in this room, for purposes of organization, now close upon four years ago, almost the first question that was introduced to our notice was that of patent reform; when Mr. C. J. Kintner of the Patent Office presented a spirited appeal to us for aid in bringing about certain reforms which he then deemed necessary. Since that time we have had valuable and forcible papers presented before the Institute by Mr. Frankland Jannus and by Mr. A. C. Fowler, both of whom brought out very ably the necessities of the situation at the time. It will thus be seen that the Institute is well prepared to consider the subject in all its bearings and relations, and is ready to learn from Mr. Steuart just what work the National Electric Light Association now proposes to do with regard to the bill to be introduced before Congress. I may say here that I have myself had the opportunity of attending all the meetings of the National Electric Light Association at which this question has been brought forward, and I think I may take the liberty of saying that that society does not intend to act with any undue haste or precipitancy in the matter, but is likely, in fact is sure, to move with its accustomed practicality and business-like common sense. Our position to-night is one in which we may be able to do great good in the direction of showing how far this movement is calculated to receive support and sympathy in scientific and professional circles, especially in those that are connected with electrical interests. I have much pleasure, therefore, in asking Mr. Arthur Steuart to read us his paper on revision of the patent law.

Mr. Steuart then read his paper. (See page 9)

The President—Mr. Steuart's weighty paper is now before us for discussion. On such an occasion as this, when there are so many views to be represented, we shall be very glad to have the participation in the discussion, of gentlemen who are interested, but who may not be members of the Institute; and before we proceed further, I think I express the general wish when I call upon Mr. George Ticknor Curtis to open the discussion. Mr. Curtis is known to all of us as a foremost student and exponent of patent law in this country, and it would be of the greatest usefulness to us all to learn from him what are his views of the subject in general, and what are the specific points to which he considers it best for us to direct our attention in seeking any reform of the system.

Mr. George Ticknor Curtis—Mr. Chairman, I have listened with the greatest interest to the very able and comprehensive paper which has been read. It is a subject that has occupied my thoughts and exertions for a good many years. A year ago last winter I caused to be introduced into the House of Representatives a bill, which I drew, for the appointment of a commission having the same general object and purpose as the bill which you contemplate. The especial features were a little different. I did it on my own responsibility, but I did not do it without consulting others. I consulted the Commissioner of Patents. I consulted one or two of the Judges of the Supreme Court of the United States, and other persons. The bill was referred to the House Committee, and they gave a hearing on it to me and other gentlemen. The Commissioner of Patents attended, and he urged more especially in regard to his own department the importance of the bill, and had a great deal to say, especially on the subject of the establishment within the Patent Office of a special tribunal, such as has been sketched in the paper that has been read this evening. The bill met with great favor with the House Committee, and they unanimously voted it, after making some modifications in a few of its details. They changed some of the provisions in respect to the compensation of the Commissioner and provided a suitable compensation for a secretary, and they made a distinct appropriation, I think of the sum of $40,000, to cover the entire expense. The bill was reported in the House, but it was overslaughed with thousands of other bills that never passed that Congress. I happened that winter to have a good many cases before the Committee, as counsel or associate counsel, and I became very intimately acquainted with the different members of the Committee from different parts of the country, and I am persuaded that if this association and the National Electric Light Association shall take up this subject and resolutely carry it before Congress in the mode in which you contemplate, that you can get the bill passed. That bill in which I had some instrumentality fell to the ground of course at the expiration of that Congress. I had a conversation with Senator Platt, of Connecticut, who is the chairman of the Senate Committee on Patents, and he raised this objection, that however good a code or bill might be prepared by such a commission, that when it came to be enacted in Congress, it would be loaded down with amendments that would kill it. Well, my answer to that was, that would depend on the ability of the Commissioners to make a consistent and harmonious code and one that would address itself, on its own merits, to the general legislative mind; and that it would also depend upon the ability of the Commission to explain the changes which they contemplated, or the improvements which they contemplated, in a report to accompany the bill; and I thought that if that could be done a majority of both houses would see the wisdom of passing it as it was presented by the Commission, and not undertaking to amend it, but let it go into operation and be amended as the progress of time should show amendments to be necessary. This matter was never before the Senate Committee. This was simply an informal and private conversation which I had with the Chairman. Now, sir, it would take me half the night to touch all the points, or half of them, on which it seems to me the time has come for this kind of action. My situation and occupation of late years have led me to bestow a great deal of attention on the course of the Supreme Court in the administration of the patent law. Unfortunately—I do not know how it has come about, exactly—but the present court has gone to very great lengths in overturning all the great doctrines of the patent law that were settled forty years ago when I first began to practice—and that is more than forty years ago. There have been decisions, which of course must stand as the law until Congress shall interfere and declare the law otherwise. Well, that is one great part of the task which such a Commission would have to perform. They would have to examine all these cases and see whether they are or are not consistent with the fundamental principles of the law as it has been construed heretofore. The statute law is substantially the same to-day as it was when enacted in 1838. There has not been any very material change. But there is a very great departure in the doctrines that are held now by the Judges of the Supreme Court from what seemed to me to be the sound and true doctrines of the law, and I hope you gentlemen will go ahead and get your bill passed and then secure as suitable a commission as you can. I have a copy of the bill of the last session, which I will hand to the President. I suppose that your bill, which in some respects is a better one, will go at once to the House Committee, and of all suggestions I should respectfully recommend that you avoid the appearance of aiming at any particular point, any particular change, in the present system of patent law more than others. The paper goes over a great deal of ground, specifies a great many different points. Well, there would be a difference of opinion, of course, about those different matters. In a great deal of it I agree. I do not know whether I should agree with every part of it, but if you can present your application in such a way as not to allow the Committee to have the idea that you have any axe to grind for yourselves or anybody else, in respect to any specific question, why I think there is no doubt but that you will succeed in carrying the measure that you wish to.

The President—It has been very interesting indeed to have these remarks from a gentleman so well known and whose experience extends over a period of well-nigh half a century. In listening to such mature advice and in governing ourselves by it, we certainly cannot go very far amiss. Mr. Curtis in his remarks made allusion to an interview that he had had with Senator Platt. I may state that a few days ago I wrote to Senator Platt, calling his attention to this movement which had been set on foot by the National Electric Light Association and which we proposed to bring within our purview, and I asked his opinion of it, saying that we would be very glad if possible to have his attendance at the meeting. I would like to read his reply. It is as follows:

U. S. SENATE, Washington, Dec. 17, 1887.

T. C. Martin, Esq., Prest. Am. Inst. Elect. Engrs., New York:

Dear Sir—I have your letter of the 15th, expressing your desire that I be present at your meeting next Tuesday evening in New York. It will be impossible for me to leave Washington at that time.

With regard to the proposed revision or amendment of our patent law, I can only say, generally, that while I think some amendments are very desirable, it is very doubtful, first, whether such amendments as are desirable can be obtained at the hands of Congress; and, second, whether any attempt to radically amend our patent laws would not result in the passage of laws calculated to injure the interests of inventors and the public. I say this, because my observation leads me to believe that probably two-thirds of the Members of Congress are more or less prejudiced against patents and against certain desirable features of the patent system, and during all my experience in the Senate it has been my effort to prevent Congress from passing laws which would be disastrous. No man can predict the outcome of an effort to amend the patent law. It may result in what we deem the advantage of the public. It is quite as likely to result injuriously to the public. I have been made to feel very many times that perhaps it was "better to bear the ills we have than to fly to others we know not of." In saying this I do not mean to imply that I am not in favor of amendments, but simply to indicate the danger that always confronts us when we attempt to legislate with reference to patents. Very truly yours,

(Signed) O. H. PLATT.

We have a representative of Connecticut with us in person this evening. I refer to Mr. Albert H. Walker, and his views on this subject would be likely to interest us very greatly.

Mr. Albert H. Walker—Mr. Chairman and Gentlemen—I have listened with great pleasure, as we all have, to him whom we regard as the father of us all, speaking of those of us who are patent lawyers, or are interested in the development of the useful arts. The pamphlet that I see in the hands of some of you, and which I suppose has been read by most of you, contains an article by myself which sets forth the principal part of my views touching the desirability of revising the patent laws. It will therefore not be expected that I shall elaborate my opinions upon the subject on this occasion; but I shall be glad, with your permission, to make some observations touching the expediency of pressing the bill to revise the patent system. I do not agree in the slightest with Senator Platt. My experience in the attempts that have been made to secure from Congress the revision of the patent laws, dates to a considerable earlier period than that of Senator Platt, and with all deference to him, I think it has been more extensive than his has been, because during his occupancy of a seat in the Senate no such effort of any degree of seriousness has ever been made. Ten years ago now the celebrated bill 300 was before Congress—the 45th Congress. Its herald, its John the Baptist, its forerunner, was before Congress 11 years ago—the 44th Congress—and very strenuous effort was made to pass that bill. Very large amounts of money were expended in employing distinguished lawyers to go to Congress and secure the passage of the bill. It was not at all favorable to the patent system as a science. It was advocated by men who had axes to grind. It was advocated by men of very great ability who had clients who contemplated plucking certain prospective prey of theirs, and it failed, because it was a bad bill, and I think that a bad bill can be relied upon to fail in the American Congress, upon the subject of the patent laws. A great many have failed, and I think they all will fail. Why?—Because there are so many intelligent men in Congress, and because there are so many intelligent men in the United States who can explain things to the intelligent men who are in Congress. If we are ever going to make an effort to secure a revision of the patent laws, no time is more opportune than this. I read this afternoon, on my way here from Hartford, an editorial published in the December number of THE ELECTRICAL ENGINEER, taking the view of this subject which is taken by Senator Platt in his letter. The Senator indicated in that letter his opinion that a Congress which sits pending a presidential campaign and pending the counting of an electoral vote, is a very inopportune Congress to which to apply for a revision of the patent laws. But half of our Congresses come within that category. Half of your Congresses sit in the last half of a presidential administration, and the other half in the first half of a presidential administration, and those Congresses which sit in the last half of presidential administrations are generally understood to attend chiefly to presidential elections rather than to the public business; and for that reason the editor of THE ELECTRICAL ENGINEER expressed the opinion that it is hopeless to expect anything in the way of important legislation from that Congress. I am inclined to agree with him, and therefore I advocate that that Congress be the Congress that be invited to pass the bill providing for a commission, and that the 51st Congress, which will not be trammeled by such considerations, be the Congress that be invited to enact the bill which shall be recommended by that commission. It is impracticable, in my judgment, to secure from any one Congress the passage of the bill to appoint a commission, and also the enactment of the legislation which may be recommended by that commission, because the time which passes after a particular Congress assembles and begins business before that Congress adjourns is less than fourteen months, and that time is too short a time in which to secure the passage of our bill or of any bill for the appointment of a commission, and for that commission to pass through its deliberations and produce its report and have Congress to intelligently act upon the bill which may be recommended by that commission. In point of fact those three things never will be done in any one Congress. Therefore the obvious plan is to ask one Congress to appoint a commission or provide for the bill appointing a commission, and the succeeding Congress to pass upon the legislation that may be proposed by that commission, and that is the scheme of the bill which appears in your pamphlets as having been advocated by the National Electrical Light Association. That bill is proposed to be introduced into the 50th Congress, and the report of the commission is proposed to be submitted to the 51st Congress, so that no time more opportune than the present will ever occur for us to move in this matter. Senator Platt has suggested the inexpediency of a commission, holding it more expedient to apply to Congress to pass particular legislation on the subject. That plan is far more likely to do harm than to do good, because such a particular bill to amend the patent law in a particular way is the very sort of a bill that will be loaded down by amendments. It will come before Congress with no responsible authorship back of it. It will be an anonymous bill. It will rest under the suspicion of having been gotten up by men with private interests to serve. It will be presented to the committees in Congress, and the committees in Congress will not understand the subject, and they will think they can improve this bill, and they will take a whack at it and put on a patch here and cut out a piece there, and finally when that bill is presented to Congress it will resemble nothing "in the heavens above, or in the earth beneath, or in the waters under the earth," and after it has been amended by the individual members it will bear a still less resemblance to any of the works of nature or true art; whereas a bill presented by a responsible, authoritative, respectable commission will have weight. It will remedy grievances which are justly complained of by those who are somewhat prejudiced against the patent system, as well as remedy evils under which those labor who represent the interests of inventors. These bills that have been introduced for the purpose of striking a blow at the patent system during the past five, six or eight years, have all been of one character. I have closely watched them. They are bills which provide that no suit for infringement shall be sustained against anybody for merely using a patented article which he purchased without actual knowledge that it was covered by a patent. These terrible grangers from the west that are represented as being willing to come down on the patent system the moment they are let loose, like the angel of death, have never made any attempts more extreme than that, and they have made their attempts a little more extreme than they would have made them if they were instructed on the subject a little better. They had a grievance on that point, and that grievance has chiefly grown out of the driven-well patent. But that grievance has been removed since the late decision of the Supreme Court on the subject. Mr. Andrews appointed agents to travel hither and thither through the western states and pounce on farmers who hired well drivers to put down wells, in total ignorance of the existence of the patent, and for which they demanded of them that they pay exorbitant royalty and had brought suits promptly against them, and then had added to the original amount a considerable sum for counsel fees and marshal fees, and what not, until the farmer had concluded he would have to mortgage his farm to get rid of that driven-well agent. That has stirred up a good deal of odium in some parts of the west, and members of Congress have thought they were serving their constituents splendidly by introducing bills providing that nobody shall be held liable for the use of a patented article that he purchased for himself without knowledge that it was covered by a patent. Now those bills have been too broad and sweeping. They could not be scientifically introduced into the patent laws without working inharmonious results, and those results were not foreseen by the men who advocated them. Now I believe firmly that if an intelligent commission had this matter in hand, one of the things that commission would do would be to draft a measure upon that topic, going as far as the just requirements of the grangers would carry them, and not going as far as the representatives of the grangers in courts have gone, and that those sections thus drafted would meet that ground of complaint and would be seen to meet that ground of complaint by the very men who have made the complaint. Now I have heard considerable ever since I attended before committees of Congress ten years ago, about a great deal of opposition to the patent system. This opposition to the patent system is like the fever-and-ague you had out west—it was never in the particular town you were in, but you could always find it in the next town. Now it has happened to me to draw the pleadings, or otherwise participate in patent litigation in every state of the Union, except five, and to argue cases orally in fourteen of the states of the Union, and I have lived among a wide variety of people. When I was a small boy my father took me from my New England birth-place to Wisconsin, into a purely agricultural community, a newly-settled country, where the painted Indians used to whoop by our house in the summer-time, and where there were no manufacturing interests, and I say to you gentlemen that I never yet met a solitary man in my life who was opposed to the fundamental principles of the patent system—not one individual. I have met the wild, untutored Congressman from Texas and from the western states, and I have met all classes and conditions of men from Massachusetts to California, and I have yet to see the adult voter who was opposed to the underlying principles and general framework of the patent laws. It is all imaginary. I have talked with Senator Platt about it, and Senator Platt has always adopted this mode of operation. If we get a bill sent up from the Senate to the House on the subject of the patent laws, throttle it, pay no attention to it, smother it in committee! That is the way he has done business. He has been in Congress at the head of the Committee on Patents. We have not had a solitary line of legislation, good, bad or indifferent, on the subject of patent laws, since 1875, and since 1879 there has been no serious attempt to remedy the evils under which the inventors of America have labored. This is a great wrong, and the United States Senators and Members of Congress have much to answer for. So that I see nothing to fear whatever from the appointment of a commission, but everything to hope from it, and I firmly believe that if a commission was appointed the head of which might be my own predecessor as a writer of patent law text-books, Mr. Curtis—if such a commission were appointed to sit as judges, to do justice according to their knowledge of patent law, between different classes

and conditions of men, between the inventors and the users of patents, the report of that commission would be seen to be so eminently fair, so eminently sound, that it would go through both Houses of Congress without serious opposition, without any attempts at amendment that would be more harmful than a fly upon the trunk of an elephant, and without any changes whatever. Whereas if we continue to content ourselves, or endeavor to content ourselves, with the outgrown clothes that we have tried to robe ourselves in during the past fifteen or twenty years, we will stumble along after a fashion, and the world will not collide with any other planet, and inventors will get some sort of reward for their inventions; but there will be a great deal of trouble, a great deal of unnecessary loss, and a great deal that ought to be avoided. In these days, when the arts are being so perfected, it is disgraceful to the United States that the patent laws are not also being perfected. What would anybody think of the suggestion to do away with dynamos by reason of the fact that they were more dangerous than a Morse telegraph sounder? In like manner, how can we estimate our courage at a high rate when we are at all restrained by the opinion of Senator Platt, or anybody else who entertains such an opinion, from doing what in us lies to bring to the attention of the American Congress the evils under which we and those we represent have long labored, and ask that those evils be remedied?

Mr. Curtis—Mr. Chairman, I may give my friend from Connecticut a single instance such as he never met with. A great many years ago—before the war—there was a Senator in Congress, from North Carolina, Mr. Badger. He was a very eminent lawyer—general lawyer—and a most admirable person. I was conversing with him one day about a bill that was before Congress,—I do not recollect whether it was a special bill or what—but it had relation to some changes in the patent law. Well, he said, all I know about the patent law is this :—some infernal Yankee comes down to my country and mouses around my back yard and looks over the fence, and he sees something in use there in my garden, and he calls out to me and says "Stranger, I have got a patent on that; you will have to pay me ten dollars for the privilege of using it." That, he said, is all I know about the patent law, and all I want to know. Well, I said, Senator, you are here to legislate for the people of the United States; you are in the highest branch of the legislative department; now that is not worthy of you or of the state that you represent. Now, you just take this subject and look into it and you will find that there is a great deal in it that you ought to know and that you ought to be able to give an intelligent vote upon. He did so, and he was entirely convinced that he ought to know something more about the subject than he did. That is the only instance of the kind that I have met with.

Mr. G. M. Phelps, Jr.—Mr. Chairman, I have a letter here from Mr. Kintner, which I will ask the Secretary to read, and after he has read it I will have a word or two to say.

The Secretary then read the following letter :—

265 Broadway, Rooms 26 and 27,
New York, Dec. 17, 1887.

Mr. George M. Phelps, Jr.,
11 Wall Street, City.

My Dear Sir:

I am in receipt of a communication from Mr. R. W. Pope, Secretary of the Institute of Electrical Engineers, advising me of the discussion touching the question of a revision of the patent laws on the 20th inst., and inviting me to be present and express my views in relation thereto. I had hoped that it would be possible for me to be with you upon this most interesting occasion, but business engagements will keep me in Washington the greater part of next week. This matter is of momentous interest to all inventors and persons interested in patent property.

Some years ago I had the honor to call the attention of the Institute to the wants of the Patent Office and the necessities of material changes in the patent law. I have noted with interest all that has been done by the society, and am gratified at the fact that the committee appointed has succeeded in putting matters in a tangible shape to go before Congress. While the scheme proposed by this committee is, in my opinion, entirely practicable, I have some hesitancy as to the feasibility of its presentation to Congress at this time, and am in hearty accord with the views expressed by you in your editorial in the December number of the Electrical Engineer.

During my official connection with the Patent Office as its chief clerk, I very naturally became pretty well versed with the political phases of all matters appertaining to the conduct of the bureau. It is needless for me to say here, that in matters of politics individual personal interests control individual members of Congress, and that upon the eve of a great national election such as occurs next November, we cannot afford to run the risk of losing everything in a proposed change of existing laws. I therefore beg that you will present the following resolution to the Institute and urge its passage :—

Resolved, That it is the sense of this society, that it is unwise at this time to seek by legislation to in any way modify the existing patent system, and that any movement to that end should be postponed until after November 1st, 1888.

I am sure that this resolution will meet with the full approval of every one who has the good of the patent system at heart.

Very respectfully yours,
C. J. Kintner.

Mr. Phelps—Mr. Chairman—I present the letter at this time because Mr. Kintner supplies a resolution and has requested that it be offered, and I offer it and move its adoption, in order to have a more definite thing before us to discuss. I have listened with great interest to Mr. Curtis and to Mr. Walker, but I am still of the opinion that it would be unwise to present the proposed bill to Congress. I think it is quite clear that there is no difference of opinion here as to the merit of the proposed changes—the changes sought to be made in the patent system through the presentation of such a bill. But in respect to the unfavorableness of the time and the public temper—I think there is much difference of opinion on that point. We had better educate public opinion further before attempting to obtain legislation. Mr. Walker has never met anybody who was opposed to patents. I have met a very considerable number of persons who have a distinct opinion unfavorable to the patent laws—unfavorable to any patent laws. I have heard a number of intelligent persons say that we would be better off if the entire system were swept away; that if the improvement of machinery and methods and processes were left entirely to the competition of manufacturers, there would be sufficient incentive to develop and improve the arts.

Mr. Curtis—Haven't they got to strike out a part of the Constitution of the United States in order to reach that?

Mr. Phelps—Isn't the provision that Congress *may?*

Mr. Curtis—Yes, but it always has been considered an imperative duty.

Mr. Phelps—Well, however unreasonable such opinions may be, there are a considerable number of people who hold them.

Mr. Curtis—You may perhaps find a great many people that do not know there is such a provision in the Constitution.

Mr. Phelps—Precisely. Inasmuch as the editorial in the Electrical Engineer has been referred to, I may say perhaps repeat here some of the points therein presented. As to this point which is brought out by Mr. Curtis that many people do not know anything about the constitutional provision for a patent system, there is an immense amount of ignorant prejudice in the public mind. The subject is not well understood; and in view of that and of the constant recurrence of these unsuccessful attempts, which Mr. Walker has told us of, to interfere with the patent law, the indications are that if an opportunity be offered for renewing attacks all along the line, it would probably be availed of to a very considerable extent; and it is not at all unlikely that a very large number of members of Congress would be very greatly influenced by public opinion hostile to patents. If we could feel quite sure that the commission would be headed by Mr. Curtis, and composed of men like him and Mr. Steuart, we should have no hesitation as to *their* part of the work. The hesitation comes in as to what would be done with it after they had formulated it, and it seems to me we have little to expect from any early Congress. The bills to reform other features of the national polity have not always fared very well at the hands of Congress. I do not know why we should feel certain of having wise and discriminating action taken by that body upon a measure to reform the patent law.

Mr. Walker—The last tariff law came from a commission.

Mr. Fowler rose to speak—

The President—I would like to ask Mr. Fowler to preface his remarks with a few of the statistics he has recently compiled with regard to patents covering electrical inventions.

Mr. Fowler—I have understood from good authority that three-fourths of the manufacturing interests of this country are based on patents, and I think that in the electric art we can safely say it is nine-tenths, because nearly every electrical appliance is patented in one way or another. Up to date there have been 375,000 patents, and nearly 12,000 of them are electrical patents, say one-thirtieth of the entire number. Most of these electrical patents have been granted within the last 10 or 12 years. About 25,000 now issue yearly—and about 30,000 applications are filed. In the electric art there are about 4,000 electrical applications a year, or about 75 per week. I think this will show the importance of this subject to electrical men. It would be safe to say that almost 10,000 of the 12,000 electrical patents that have been granted to date have been granted within the last 10 or 12 years, averaging nearly 1,000 electrical patents for each year during the last 10 years. Before taking my seat I should like to say something upon the paper that has been read this evening. I stand here as a representative of—I do not know but it may be called the patent office mill—I have been through it and I have been in the electrical part of it. Mr. Steuart, I think, has dropped into an error in respect to the Patent Office paying all its expenses since its organization. In a paper which I had the pleasure of reading before you a year or so ago I mentioned that the assistant commissioner had looked up this point. In years gone by the printing that was done for the Patent Office was done by an appropriation of Congress and not out of the Patent Office fund. Recently the expenses of all printing have been deducted from the Patent Office fund. This assistant commissioner, 10 years ago, I think,

ascertained that including the cost of printing, the expenses of the Patent Office would have been about equal to the amount of the receipts. From the speaker's remarks this evening one would be led to believe that there was no such thing as an examination in the Patent Office for admission. I can tell you all that there are some examinations held in the Patent Office, and pretty hard ones too. I have seen graduates from the Yale scientific school, from the Princeton scientific school, and from the various scientific schools of this country, and from West Point, come down to the Patent Office. They were going to get in, but I have seen a great many of them—the most of them—go back. The examinations they hold there are quite technical. I have been through them, and I have had to study very hard to get through them, and I started with a good scientific education. It has also been the practice of the Patent Office in years past to make the examination include questions on patent law; formerly nearly all the questions were on patent law. Latterly they have been directed more to scientific subjects. For promotion in the Patent Office, the questions are largely those of practice and patent law. Among the examiners will be found a great many who are quite well versed in the law. There are in Washington three night schools turning out lawyers by the hundreds, and a great many examiners in the Patent Office are students in those law schools. The speaker takes exception to one examiner ruling differently from another. You will find the same thing in the courts. The questions that arise in the Patent Office among examiners on applications are not so much questions of law as they are questions of fact, and where you find questions of fact you will find men differ. It is an old saying, "So many men so many opinions." It is true in the Patent Office, and I do not see how it will be possible to harmonize the rulings of such examiners. Of course an *ex parte* proceeding does not bind every one. It is well known that an application for a patent is an *ex parte* proceeding. It is not contested at all, and it is no wonder that they are sometimes overturned in the courts, and I think there is a presumption in favor of a patent always. I think the courts recognize a *prima facie* right when there is a patent. This question of Patent Office reform is a question that has been studied within the Patent Office. The examiners have made a great study of it. Some years ago they took steps in this direction. It was in the particular direction of an increase of salaries, and of course that was considered a salary grab, and it was not very successful. The speaker has enumerated a large number of objections to the patent laws that are highly visionary. It strikes me that the system as a system with some few exceptions is a very good one. I heartily concur with him in the wisdom of establishing a patent court, and I think he will find that the Patent Office itself desires such measure. Almost every one believes that the judicial functions of the commissioner should be taken away and his office made purely executive. It strikes me as far as the Patent Office is concerned there are only two things the matter with it. One thing is the inadequate pay of examiners. If the pay of an examiner is increased, say doubled,—I mean all through the assistants,—the tendency will be that men will stay there, and a man that has been a long time in the examining corps can perform three to four times the amount of work than one who has been there for a short period can do. It strikes me that this is the one thing needed in the Patent Office, increased pay, and there might be an increase of force. As to the appointment of a commission it seems to me that the patent law could be revised by direct application to Congress. There is a standing committee of the House, and there is a standing committee of the Senate, and the chairman of the Senate Committee is ex-secretary Teller, of the Interior Department, who knows all the Patent Office workings and who has in times gone by had a great many cases of appeal to him from the Patent Office, before his jurisdiction was overruled by the Supreme Court of the District of Columbia; and I think that if the National Electric Light Association, were to appoint a committee to confer with the patent committee of the Senate or of the House, that reforms could be effected more readily than by appointing a commission. It is a more direct application of power than the other way, and I think we all believe in applying power just as directly as possible.

Mr. Phelps—Mr. Chairman, on one point I wish to add to what I have said. I have had some conferences with other persons in taking a position on this matter. I have not trusted merely in my own views and apprehensions. I have been told by an attorney of prominence and large experience in patents as well as other branches of the law, that he went to Washington some two or three years ago with the express purpose of initiating a measure to remove the very objectionable limitation of United States patents by foreign patents; and that having consulted with various persons in and out of Congress with respect to the matter he concluded that he had better say nothing whatsoever about it, better drop it. In his judgment there was danger then of inviting attacks on the patent system, through amendments and otherwise, even in respect to such a specific measure as that alone. I confess that incident has influenced my mind very considerably in forming an opinion upon the expediency of the measure before us.

Mr. T. D. Lockwood—I stand before you this evening the representative of perhaps the best contested patent in the world—the Bell telephone patent of 1876, and yet I like the patent law of the United States. I am not in the best condition to talk, because I have not heard the previous discussion and I have not heard the paper, and I have just come from a dinner of about 14 courses. Nevertheless, as the last seven years of my life have been spent with greater or less success in studying patents, I thought it right that I should say a word. With all the evils of the patent law of the United States, it is yet the best patent law in the world, and my experience is that the patent law is not one-tenth as immoral as patentees themselves are. One man gets a patent for a steam engine. It is the first time perhaps that a steam engine has ever been invented. Another man gets a patent for a crank (*a*), and fastened down to the end of the main shaft (*b*), and attached to the reciprocating connecting rod (*c*), with a brass bushing in it (*d*); and the second man cannot comprehend for the life of him why he has not got the right to use the steam engine, and he goes ahead and uses the steam engine, and a suit in equity is brought against him, and when a preliminary injunction is obtained he poses before the world as a martyr to inefficient patent laws; and then he goes to work and makes a slight variation in his patent, and gets perhaps a new element in the same old claim, and goes on infringing, and he is prosecuted again, and is enjoined again, and he poses before the world as a double martyr, and then gets a few more of his kind together, and they form an association for the protection of patentees. Then a few gentlemen who really are patentees think it would be a good thing to be protected also, and for the sake of their own virtuous patents they combine themselves with the immoral patentees, and get a pretty good lawyer, sometimes a first-class lawyer, to frame a bill, and it usually is to protect the innocent purchaser, and the innocent purchaser nine-tenths of the time knows very well that he is purchasing a patented article, because it has got the patent stamp very likely so emblazoned on one side of it that he cannot put it straight on the wall to save his life, but it has got to be hung bias. For these reasons, and many more reasons, I believe that we better let well enough alone. I have noticed in the last seven years that whenever Congress goes to interfere with the patent law, they interfere with it the wrong way. Two-thirds of Congress have got the notion which prevails in Wisconsin and Minnesota and the northern side of Dakota and Idaho, and a few more places like that, that the patent system is nothing more nor less than a system of wholesale swindling, and I was very glad to see by the Supreme Court decision last May, on the driven well patent, that the Supreme Court of the United States was not going to be influenced by popular notions or popular sentiments. I was glad to see that the Supreme Court could sustain a righteous reissue. Even now the present Congress, which has not been in existence much more than a week, has begun to get in its work. I noticed last Friday morning that the regular innocent purchaser bill had already started on its march. I am very much of the opinion of Mr. Phelps and of Mr. Kintner that at the present time it would be unwise to try to get any patent legislation. I am sure that if we stir the matter up we shall stir it up more than we want to. If we get a commission, our worthy President, with the best intentions in the world, will nominate two commissioners from Michigan, and two commissioners from Indiana, and one commissioner from Ohio, and I am very sure that that commission will consider it its duty to point out what one gentleman very forcibly did this evening, and say that the Constitution does not provide for a patent law; it only provides that there may be a patent law, and condemn the ignoring of that article of the Constitution which intimates that if there is a patent law it shall be to promote the arts and sciences. I am very glad that in these days of corruption, of judicial corruption, we have in the courts of equity, upright judges, judges that are well versed in the law, in patent law, and who usually keep that provision of the Constitution before their eyes, and keep the idea of that article of the Constitution before their eyes, that a patent law is not to oppress people who use useful instruments, is not to provide that certain advantages and certain monopolies shall be given to certain people, but that in consideration of some useful thing furnished by an American inventor, that man shall be protected in the manufacture of his invention for a certain limited period. Now, with respect to the Patent Office, we cannot deny that there is a good deal of inequality of practice, notwithstanding the eloquent defense made by the gentleman on my left. Those of us who have practiced before the Patent Office have sometimes had the ill-fortune to have a case before three successive commissioners, either by an interference or by a double interference, or by some patentee who comes in at the very last minute, or by the inability of some examiner to distinguish between matters of form—matters of law—and the real subject of the case in the class of electricity. Since I have begun to send applications to the Patent Office we have had the immortal Wilbur as first examiner in the electric class. We have had H. C. Townsend. We have had Dr. F. L. Freeman. We have had Mr. C. J. Kintner, and now we have Mr. Brown. Every one of these examiners to my certain knowledge has made different rulings upon the same point with the best intentions in the world. Mr. Wilbur used to make rulings I think that would help his own pocket out. Mr. Townsend was about as fair a man as I ever knew. Dr.

Freeman was first-class, but a little indisposed to work. Mr. Kintner always recognized the difficulty of formulating a proper electrical claim, and allowed considerable latitude. Mr. Brown, filled from the sole of his foot to the crown of his head with law, but knowing very little about electricity, is disposed to stickle for matters of form. It may be that the gentleman is here. If so, I assure him that I do not mean any disrespect; but he came to the class of electricity from the class of hydraulics. Now how can a gentleman, no matter how good a lawyer he is, become an accomplished electrician in the twinkling of an eye, simply by being transferred from one part of the Patent Office to another? I do not know. It may be that he passed the competitive examination spoken of. If so, I have nothing more to say. If he passed it, all is well. I hope when Mr. Brown has fully learned electricity, and learned it well, that he will stay there, and that by that time we shall have some provision, either with law or without law, whereby examiners are well paid if they are good ones. I have nothing to say against Mr. Brown's rulings. It would be a benefit if we could get some uniformity, and if we could get Congress to allow the Patent Office to spend the money which the Patent Office earns. Once more I wish to express my opinion that it is not wise, in the year before the general election, to stir up any general legislation on patents, and I do not think that a commission is the best way to do it. I think we shall have to go straight to Congress and get some kind of a law which is formulated after mature deliberation and consideration by all those having an interest. By a congress of patentees, if you will, with the best legal talent we can get.

Mr. Frankland Jannus—I do not think that after all that has been said there is much more to add relating to the patent law itself. I agree with Mr. Lockwood that it is a very excellent thing as it stands, and as the matter appears to me there are only a few details that need immediate attention, and those I think are urgent. I refer first to the entire divorce that I think there should be between American and European applications. We do not pay much attention to European law. European countries do not pay any attention at all to ours. And why we should be hampered by them I never could at all understand. Now there is no better illustration of the danger of meddling with the patent law than what comes in connection with foreign patents. Take the matter of the international convention. That thing has been fixed and yet it is absolutely inoperative for the reason that our representative did not know the difference between the filing of an application and the granting of a patent. Now as I understand it to-day if you can get a case into the office and if you can get it through inside of six months, then you can take advantage of the balance of the seven months, otherwise it is of no importance to anybody. That is just a trifling example of the intelligence and information displayed by our legislators on patent matters. No doubt the person who conducted the United States negotiations was perfectly sincere in his intentions. But the result is not good. Then after that matter has been disposed of we want something in the matter of reissues. Mr. Lockwood has referred to a righteous reissue. It is hard to say what that is. It seems to me a reissue is righteous when the Supreme Court of the United States says so and not until then. I think that a great many of the difficulties and troubles from which we actually suffer exist in the Patent Office. I have thought so for a long time and I think so still. I think that reform is needed and we do not want to go to Congress for that because we will get nothing. If Congress will do anything about the rules of practice I would like to have them, but I doubt very much that they will. I have never yet known of an instance where an examiner was ousted for incompetence, and there is not a man here to night who has practiced before the Patent Office who does not know that there are many examiners who are incompetent. Many are competent, I admit that; but incompetent ones exist. There are men in prominent positions in the Patent Office to-day who got in before the examinations began. They could not pass an examination to get in now, if they were once out, and the only course for a man when he knows his application is being considered by such a person, is to wait until the chief comes back and get it into some other hands, because if a man has got your case pigeon-holed you are stuck right there. You cannot do a thing. The only thing is to wait until you can get a change of venue in some way or other.

Now we all appreciate the supreme importance of a record of previous cases in considering the validity of a particular patent. We all know that we have to go to the original files; it is there we get the original information. We want to look at the references, etc. Now it is a fact that when you go back of a few years you cannot find a complete file in the records of the Patent Office. I do not mean to say there are none, but I mean that back of the few years the files are very incomplete. They contain the specification and letters and probably a printed copy of the specification, but no drawing. Then as the record room is about a mile and a half away from the file room, there is only one single mode in which you can get the whole case together, and that is, to buy copies of everything you want in order to be able to look at them altogether for about 10 minutes. I once called Commissioner Montgomery's attention to the matter. He said, "Why certainly,—Mr. Duryea won't you see to it that these copies are put in these files?" I felt that I had accomplished something. I went up there again in a few weeks and asked somebody if he had heard of this being done. It had not been heard of. I went to see the commissioner again. He scratched his head and seemed to try to recollect, "Oh, yes, Oh, yes," he said, "Mr. Jannus, if you will put that matter in writing I shall be ever so much obliged to you." I proceeded to do so. In the course of a few days I received a very courteous reply which said in substance, "that the matter referred to in my communication of such and such a date had been referred to a committee consisting of the chief draughtsman, the chief clerk and one of the principal examiners, and that they had decided that, whilst it was very desirable that this thing should be done, still that there was no force at the disposal of the commissioner with which to accomplish the same; that it was eminently desirable, but that it could not be done, and he kindly concluded with the suggestion that I call the attention of his successor to the same thing. I do not know whether his successor has got around to that or whether he ever will, or whether I ever shall. I think that the surplus of which we have all heard so much ought to be applied to attending to that matter.

I remember once being particularly struck by the effect of the statement on my part that the Patent Office was responsible for nothing and responsible to nobody. I got to thinking about it afterwards myself and the more I think of it the more I appreciate it—it is a fact, and it is that irresponsibility that gives rise to a good many very peculiar actions. It does not make any difference how much an examiner annoys you, or impedes the progress of your case, there is absolutely no responsibility on his part. There is nothing he can do, judging from the history of the office that will secure his dismissal or reprimand or anything whatsoever! The only thing you can do is to appeal. That it seems to me ought to be remedied in some way. A man goes to the Patent Office with a case; he is instructed in the art and he knows it is new. His attorney kows it too, of course, as his client has told him. Well, the case is taken up by some junior, some new man, probably in the office only a week or two,—which very often happens—especially in the case of electricity. Now the reference is not well considered and the burden is thrown entirely upon the attorney and his client to demonstrate to the office, to explain to the examiner, what the reference does show, and then call attention by contrast, to what the application shows. That is a thing of daily occurrence. I think that after a man has shown evident incompetence that he ought to be incontinently dismissed. I think there are plenty of good men to be had. Now it is a regular thing for a fellow to examine a case and fling a lot of drawings at you and let you fight it out yourself, afterwards. I do not think that that is the intention of the rules. I do not think that is what ought to be done. I do not say it is done in every case, but it is done in too many cases, and it is these things that keep the work of the office back and hamper and annoy everybody connected with it. I have seen men deliberately order their attorneys to take claims out after their attorney had advised them that they ought not to take them out.

Then this shifting of examiners from division to division is another source of delay and trouble, as in the case of electricity, where the chief examiner comes from water works to electricity. It practically blocks the progress of a class for a long time. Then, when you come to add his lack of familiarity with the subject, his overwhelming disposition for technicalities, why, altogether, you get a very interesting combination.

Now in the division of chemistry there is a gentleman, a very nice fellow outside of the office, but then he is always ready to deny the operativeness of a process. He is not going to find out whether it is operative or not. The fact that he will in all probability be proved wrong has nothing to do with the case. You have not proved that it is operative. You have not submitted specimens, and that is the end of you until you do. I have cases there now and I know that they are operative. The man who says they are is a man of fifty years' experience; yet this official with no experience at all outside his room says it is not operative, and the case is clogged until it becomes convenient for my client to prove otherwise. Now I have heard it suggested by a friend who has been very highly spoken of here to-night, that the day of a close examination in the Patent Office was gone, that the system of examination—the system at present theoretically in existence—is obsolete. His idea is that the examiner should take up a case, point out objections—insufficiency of descriptions, and all those things just as he does now, and then cite all the references he has got tending to show the lack of invention; that after receiving those references it should be the duty of the applicant to amend his case as he might see fit; take out his claim, limit it, expand it, do anything he chooses, and then send the case to issue. That struck me at first as a most iniquitous proposition; but I think it will bear consideration, because the courts will be the ultimate tribunals before which that case will be settled. For when the office has cited its references then that branch of the case should be closed and sent forward. The applicant takes the risk in it. The favorable dictum of the Patent Office does not hold before the court. I think that there is where the responsi-

bility falls in view of the fact that the courts constitute the only ultimate tribunal. It is not customary for people nowadays to put money in patents without at least looking at the file, and the moment that is done they are in possession of the data upon which the courts would have to decide and upon which they might as well decide also.

I certainly agree with Mr. Steuart that the patent law needs some revision, but I am a little doubtful in my mind whether this is the best time to do it or not. Some think it is; some think it is not. I think if we were to go for two or three inoffensive amendments we might get them. If that cannot be done, as many gentlemen seem to think, then I favor the plan of a commission, because this thing of going to Congress always gives rise to the suspicion that the parties who go have an axe to grind. The question is, how can these lawyers afford to come here and ask for these things? People in Congress ask these questions as well as other people. The answer naturally is, they are trying for legislation for some particular thing, and especially are politicians liable to those suspicions. They think of that first, last, and all the time, judging from what they say, and for that reason I think the plan of a commission would be the best, because the matter can then be presented to Congress in an impartial manner. Whether this present time is or is not the best I do not know, but I think if it is decided to apply for a commission that this time is as good as any other, because it will certainly take them time to consider the question, and to formulate what they want, and before they get any hearing from Congress, and I doubt very much whether the matter could be brought to the attention of Congress until after this bugaboo of the presidential election has passed.

Mr. Lockwood—I crave your indulgence for one or two remarks. Words would fail me if I should attempt to depict the interest with which I have listened to the remarks of Mr. Jannus; and while I cannot agree with every one of his propositions, I may say that I can cordially agree with some of them. For example, I can agree most cordially with his proposition that the aspect of our patent law with relation to foreign patents does need revision. But I do not think that a commission is the best means of accomplishing it.

With respect to the reissue question I do not think that the law needs any revision.

Mr. Jannus said that he never heard of any incompetent examiner being dismissed. I never did either. I do not think anybody ever did. It is the competent examiners that get out of the Patent Office. It is the incompetent ones that stay in. But I would like to add a doxology to his remarks there. I think it is equally necessary that there should be some kind of an examining committee for attorneys. I never heard of an incompetent attorney being dismissed permanently. I have known a good many to be dismissed from one client but simply to catch on to another one. And it is a pretty safe rule I think to fight pretty shy of those gentlemen who flood you with circulars after you have got a patent. It strikes me that there is something in the matter of Patent Office tribunals that needs rectifying. I do not know how the law is going to get around it, because the patentee seems to think his rights are infringed if he is not allowed to handle the tribunals of the Patent Office as he sees fit. If we get an adverse decision we feel very bad if we cannot appeal to the board of examiners in chief, and so on. So I do not know with my present information where to take hold of this subject of a tribunal. I think that needs a little more attention perhaps than has been given to it. Now we should all of us who practice before the Patent Office or are interested in patents, be prepared to bear patiently with the custom of examiners who deal with applications in an impartial and square manner. If they allow a patent which afterwards turns out to have other references and which is not new, I think we should remember that it is utterly impossible in the present state of knowledge and in the large expanse of publications and of prior patents which they have to wade through to cover the grounds every time. We have got to take our chances in the matter, and those of us who have taken out patents for inventions know we have got to get out patents for the inventor by hook or crook. As a rule the inventor does not care whether the claim is valid or can be sustained or not. If he has got a patent he can easily sell it. My experience is, no matter how foolish a patent is, how unduly broad a patent is, how ridiculous a patent is, all you have got to do is to find somebody with more money than brains and you can sell that patent, and you can organize a company with seven millions of dollars of capital on it, just as easily as you can with the best invention ever made. So I think we must not be too hard on the examiners. There are a good many ways we can help them. As a rule an examiner is open to conviction; the average examiner is, I am sure. About five years ago I filed an application for a patent before a certain examiner, which I think I could have made to cover broadly the conversion of electricity of high potential to electricity of low potential, for the purpose of getting incandescent lamps from the high potential circuits by means of induction coils, and the examiner (he was ignorant, but he was honest) said,—It cannot be done. He said, there is no such thing ever heard of as working an induction coil backward. Well, it was within the extent of my electrical knowledge that it could be done—that it had been done, for I had done it myself—and moreover I knew that the conservation of energy would work almost any way, backwards or forwards. But I had a gentleman for a client who was afraid to give me rope, and the application was put upon a shelf. In such cases as that the examiner is not to blame for sticking to his views, but the client is to blame for not sticking to *his* views. For my part rather than take a claim out which I knew I was entitled to I would let it stay in the Patent Office until the crack of doom.

Mr. Fowler—I think if the National Electric Light Association were to present some bill in Congress which would increase the pay of examiners say 50 or 100 per cent., it would go further toward removing the evils of the Patent Office than anything else combined. In one year 23 examiners resigned—about one-sixth of the whole corps. The Patent Office now is filled with new men. Until a man has examined for one year he is absolutely worthless in the Patent Office. I have been troubled a great deal myself since I have been out of the Patent Office with these questions of form, and I know exactly what it means. If gentlemen here had any conception of the work that is thrown upon examiners they would know what it means. It is a great deal easier to raise a question of form than it is to go down and examine the merits of the case. These questions of form are raised by men who are so banked-up with work that it is "anything to get rid of a case." If the salaries of these men are raised and these men are kept there who can perform three or four times the work that new or inexperienced men can perform, reform will follow. I was talking with an examiner, a friend of mine, whom I met in New York a few days ago, and he said "This is the way to work (and I thought it was a very poor one); it is anything to shelve a case." He has little rollers, stamps, that he rolls across the paper—the division, record, process and everything, *ex parte* something—he rolls them over the sheets and hands them over to the clerk, and she writes a letter. That case is got rid of. I was very much struck with this question of form when I was in the Patent Office. There was a case which had been on the merits twice to the board and once to the commissioner, and it was a case we were very much harassed about. It was a question whether the thing was patented, and one of the gentlemen in charge asked me to take hold of the case and make an examination upon the merits. I spent some little time at it and I found two English patents for exactly the same thing, and yet the case had been appealed to the board twice and to the commissioner once upon the question whether the thing was patented. That just illustrates the point exactly. They will raise these questions of form to get rid of the case rather than examine the merits, because it looks too long. They want to be up to date with the work as near as possible.

Now this question of limiting American patents by foreign patents does not strike me as being a very serious thing. Trouble is easily avoided. It is a general impression that all foreign patents limit an American patent, and yet it is only so when a foreign patent is previously issued. It is easy enough to file your foreign application on the same day that the American patent issues.

I am a believer in compulsory licenses as they have them in England. I do not think one man should be able to get a broad claim. I know my friend on the right will not agree with me in this. I do not think one man should be able to get a broad claim allowed and prevent improvers from using improvements. That is what the laws of this country gives them. In England a Board of Commissioners ascertain how much a license is worth and they make a man with a foundation patent give a license to another party so that an improver can use his invention. There are many companies in this country who have valuable improvements locked up in their safes. In that way they impede progress. I have in mind one company who say they do not want to change the machinery, although there are a great many inventions in their line that are better than the devices they use; and they buy up such patents and put them in their safe.

Mr. Jannus—I did not have the slightest intention of reflecting upon the entire staff of the Patent Office, because I know there are plenty of good examiners; I merely referred to those that were not, and to the fact that despite the examination for admission the force is not as good as it might be. I fully agree with what has been said about raising salaries, and I fully endorse the proposition that that would in a large measure modify present troubles in that respect. They want more men, and they want to have them more competent. Both things are necessary.

Now the question of reissues is a very serious one. I passed it over, as I did other matters, believing it to be almost too late to go into it, but there is one thing on that question I would like to voice—that is, the trouble in the way of an inventor in securing what has been apparently lost by a defective patent is principally owing to the fact that it is a conclusive presumption that everything that is shown in a patent and not claimed is abandoned. If there is any way of overcoming that, then we will have actually what reissues were supposed to cover. I do not believe that the reissue law was ever meant to cover a case where a man went in and expanded an application after he had found the desirabili-

ty of doing so. I do not think it was ever intended, and the Supreme Court evidently does not; but I think that if reissue is confined to the subject-matter found in the claims actually patented, giving it perhaps a better expression or some greater scope, a scope evidently due to it, and that then the applicant can remove from the defective patent the subject-matter of a different character which was not covered in those claims, then relief can be found. As the matter stands it is a fact, and I think it will not be denied, that it is almost impossible to do anything with an invention after it has been badly patented. But as I said before you never know what is a good reissue until the Supreme Court has passed upon it. That question I feel to be too deep and too serious for our discussion to-night and, therefore, will leave it.

Mr. J. A. Miller—I should like to say a few words. I have practiced before the Patent Office since 1854, and I do not know that any attorney practising before the office has been so unfortunate, particularly in one room, in his intercourse with examiners as I have been. I speak of the textile room. Now I have felt all these difficulties which have been spoken of by the various gentlemen here, and have suffered considerably. At times I was almost disgusted with the actions of some of the examiners, but about four or five years ago I had three very important cases which were rejected in Germany, and I went to Germany to appeal. Since that I have been satisfied with our Patent Office and with the practice in our office.

Mr. Jannus—An ex-commissioner had the same experience recently.

Mr. Miller—As to raising the salaries of examiners as a whole, I never did believe in that. I believe more in the European system of putting a high premium, high up. I believe in paying the chief examiners a very high salary, but I think the young men can get along with a lower salary, and I think the present salary is sufficient for them until they have striven and gained a higher position.

There is another remark I wish to make on this question of a court.

We have all suffered very much by appealing from the board of examiners in chief to the commissioner and not getting quite to the commissioner In fact we do not know where we are when we get there. The examiners-in-chief are very honest men but they get into ruts. If you have an argument before them you know just what you are to say and it depends on who is to write the opinion, and if you happen for instance, to take the question of employer and employé and get started wrong on that, you cannot win to save your life.

Mr. Davidson—I submit that there is no system for the administration of affairs among men that will not be open to numerous objections from—may I say—theoretical perfectionists. Now the patent system is not perfect; we will admit that. There are perhaps many ways in which it may be improved. There has been quite an extended discussion as to the imperfections of examiners. We attorneys are perhaps quite as much as the examiners, tainted with original sin. We are not perfect. Our judicial system is not perfect. The question we must come back to is this—is not our patent system as we have it do-day the best that we can get with some trifling corrections, and would it be wise for us to open the door to a general revision of the entire system and invite changes which will require interpretation, which will require decisions to mark down all the lines of how they are to be interpreted and overthrow doctrines in regard to patents based upon some 3,000 or more judicial decisions? I think not. As soon as a revision of the laws is invited by a commission such as has been suggested, every man with a hobby in regard to the patent law will appear or combine with others, and appear before such a commission and seek to grind his own axe. We will have before such a commission all the gentlemen who are in favor of protecting innocent purchasers. It seems to me I may be permitted to bring the discussion to what I understand to be the real point of it, that is, the propriety of making an application to Congress for the revision of the laws. Everybody assumes there are some imperfections. I should think we ought to treat them like any other business enterprise. No business man goes to another and says, I have got a claim against you; I don't know just what it is, but if you will help me to find out, I think we can get at it. That is no way to get at it. We ought to decide what we concede to be the points to be secured for the improvement of the patent system and then when we know just what we want, to go and ask for it and let the manufacturing interests, and let the inventors bring in their influence to bear upon the politicians. I believe in practical statesmanship. I do not believe in ideal statesmanship. Let us select those things which are obtainable and make a direct application for them.

Mr. Wheeler—I think that some time ago Mr. Phelps introduced a resolution, and in view of what has been said I would like to second it.

The President—Will Mr. Steuart address us again. He may wish to reply to the remarks that have been made.

Mr. Steuart—Gentlemen, I have very little to say in this matter. I came here for the purpose of hearing what you had to say, and I prepared my paper for the purpose of making a text for this discussion, and I am very glad you have so freely and so fully expressed your opinions. There seems to be a somewhat equal division of opinion with reference to the proper course of procedure. I cannot help adhering to my original view with reference to the best course. It seems to me that we can introduce into Congress a bill providing for certain specific changes in the law which is the result of the work of a competent commission who have investigated the subject carefully and who bring in a report which comes from neutral men unbiased by any personal interest, and unbiased by any special class interest in such a position that it cannot be classed as class legislation, that we will stand before Congress with a better chance of accomplishing the results that we have in view than we could possibly have were we to go now before Congress or any other time with specific legislation. While I think much good could be obtained by a bill that would provide for any one of these suggested changes which have been discussed, if a bill were introduced providing for an increase of salaries to the examiners it would do great good. If a bill were introduced for a tribunal it would do great good if it were passed, but when we are going about the thing at all it seems to me that we want to put ourselves on the floor of Congress in the strongest position that we can take there, and the way to do that, as well as I can understand it, is to go there with a report of a neutral commission, and we will have a better chance than we could possibly have by a bill prepared by any class of business, whether lawyers or manufacturers. I will say, in conclusion, that I think the resolution that has been introduced is unnecessary, because I do not know that it will have any special object or any special effect—any special purpose. The meeting of to-night was called for the purpose of having the discussion which we have here engaged in, and of seeing what was the best that could be done. It is preliminary in its general character. There will be a convention of lawyers and manufacturers held in Washington the first week of January, which will be under the auspices of the patent bar association of the city of Washington, and I will be very glad, and I am sure they will be very glad if all of you who are interested in the subject will attend that convention for the purpose of hearing the subject considered as elaborately as it will be there discussed. The meeting will last several days, and there will be representatives from several cities. I think that in view of that meeting, and of the very much more full and elaborate discussion that will there take place, any action on this resolution would be premature at this time.

The President—I think it lies within my duty to say that the resolution says "it is the sense of this society." This is a special meeting, and I do not think we could pledge the Institute one way or the other, and I would like to point out in addition to that, that we have on the secretary's desk a bulk of correspondence from some of the leading inventors and patentees and patent experts of the country, embracing various opinions, and certainly before we express a definite opinion one way or the other of the Institute, it would be well to know what lies in that correspondence which should guide our action in addition to what we have heard this evening. I merely throw that out by way of suggestion.

Mr. Phelps—I am not disposed to press the passage of the resolution.

On motion duly carried the resolution was laid on the table. The meeting was then adjourned.

The next meeting of the Institute, to be held on Tuesday, January 10, at the house of the American Institute of Civil Engineers, will be of a very interesting nature, as a paper is to be presented by Mr. Willard E. Case, of Auburn, N. Y., on the production of electrical energy directly from coal. Mr. Case, who has made extensive investigations in thermo-electricity and has succeeded in utilizing simple coal as one of the elements of a chemical battery, will give the results of his experiments and discoveries. Some of the recent thermo-electric batteries will be exhibited, illustrating practically the new departures in this unfamiliar field of research and application.

THE FLORIDA ELECTRICAL SOCIETY.

A considerable number of gentlemen connected with electrical interests in Florida met at Jacksonville, Nov. 23d, for the purpose of forming a society for the advancement of electrical knowledge among the members, the organization to include the establishment of a library, a reading-room and laboratory, also the holding meetings at which the reading of scientific papers pertaining to the subject, and their discussion, will be leading features.

The organization was perfected under the name of the Florida Electrical Society, with the following officers: B. F. Dillon, president; L. E. Spencer, 1st vice-president; W. R. Davis, 2d vice-president; G. W. Davis, 3d vice-president; J. S. Arnold, 4th vice-president; Edward B. King, secretary; D. J. Crowley, treasurer; R. B. Rood, librarian.

THE TELEPHONE IN NOVA SCOTIA AND NEW BRUNSWICK.

Through arrangements made with the Bell Telephone Co. of Canada, by enterprising citizens of Nova Scotia and New Brunswick, the telephone business of those provinces will be conducted under a single and independent management.

New life has recently been infused into the business by Mr. A. A. Knudson, of New York, who has spent some time in the provinces re-organizing the service and introducing new apparatus. The introduction of the "Law" switch-boards is said to have greatly improved exchange service at Halifax.

THE INTERNATIONAL EXHIBITION OF 1888 AT BRUSSELS.

Messrs. Armstrong, Knauer & Co., 822 Broadway, New York, authorized agents, send us a schedule showing the classification of electrical exhibits at the Brussels International Exhibition next year. The "forty-seventh competition" of the exhibition comprises "applications of electricity," and is classified as follows:

GENERAL CLASSIFICATION.

Subdivision 47*a*.—Study and teaching of electric science, measuring instruments, scientific application of electricity, lightning rods and conductors.

" 47*b*.—Dynamo-electric motors and machines. Transfer of the moving power at a distance. Distribution of the electric energy, transformators.

" 47*c*.—Telegraphy, telephony, wires and cables.

" 47*d*.—Arc and incandescent lamps.

" 47*e*.—Electric batteries, accumulators, sundry industrial applications; electro chemistry, electro metallurgy, galvanoplasty, railroad signals.

Under the head of "Proposed Questions—Desiderated" the circular sets forth in considerable detail the points of competitive examinations to be made for awards in each class.

Applications for space must be filed before January 15th.

Messrs. Armstrong & Knauer will furnish all information desired, upon application, personally or by mail at their offices, 822–824 Broadway.

ELECTRIC LIGHT AND POWER.

The Westinghouse Electric Company's List of Central Stations Using their Alternate Current System.

	Location.	Operating Company.	No. of 16 c. p. lamps.
1.	Allegheny City, Pa	Allegheny County Light Co	5,000
2.	Altoona, Pa	Mountain City Electric Light Co	650
3.	Austin, Texas	Austin Water, Light & Power Co	3,900
4.	Baltimore, Md	Brush Electric Light Co	5,000
5.	Bath, Maine	Bath Electric Light & Power Co	650
6.	Beaver Dam, Wis	Beaver Dam Electric Light Co	1,300
7.	Bennington, Vt	Brush Electric Light & Power Co	650
8.	Buffalo, N. Y	Buffalo Electric Light & Power Co	1,950
9.	Buffalo, Wyo. Ter	Buffalo Electric Co	650
10.	Carbondale, Pa	The Flectric Light, Heat & Power Co	1,300
11.	Cedar Rapids, Ia	Cedar Rapids Electric Light & Power Co.	1,950
12.	Charleston, W. Va	Kanawha Electric Light Co	650
13.	Chattanooga, Tenn	Brush Electric Light Co	650
14.	Cheboygan, Mich	Cheboygan Electric Light Co	650
15.	Colorado Springs, Col	El Paso Electric Co	1,300
16.	Columbus, Ohio	Columbus Gas Light & Coke Co	2,600
17.	Conshohocken, Pa	Conshohocken Electric Light & Power Co.	650
18.	Cornwall, Ont	Stormont Electric Light & Power Co	650
19.	Dallas, Texas	Dallas Electric Co	1,800
20.	Denver, Col	Denver Light, Heat & Power Co	6,500
21.	Duluth, Minn	Duluth Electric Light & Power Co	1,300
22.	Easton, Md	Easton Electric Light & Power Co	650
23.	Flint, Mich	People's Electric Light & Power Co	650
24.	Fort Edward, N. Y	Fort Edward Electric Co	650
25.	Galveston, Texas	Brush Electric Light & Power Co	1,300
26.	Greensburg, Pa	The People's Electric Light Co	600
27.	Hartford, Conn	Hartford Light & Power Co	2,600
28.	Hillsdale, Mich	Hillsdale Electric Light Co	650
29.	Hoboken, N. J	Hudson Electric Light Co	1,300
30.	Hot Springs, Ark	Hot Springs Electric Co	650
31.	Junction City, Kan	Junction City Electric Light Co	650
32.	Lincoln, Neb	Lincoln Electric Light Co	1,950
33.	Littleton, N. H	Littleton Water & Electric Light Co.	650
34.	Minneapolis, Minn	Minneapolis Electric Light Co	6,500
35.	Morristown, N. J	Morristown Elec. Light, Heat & Power Co.	650
36.	Nashville, Tenn	Nashville Light & Power Co	650
37.	New London, Conn	New London Electric Light Co	1,300
38.	New Orleans, La	S. W. Brush Electric Light & Power Co	5,200
39.	Newton, Kan	Newton Electric Light Co	650
40.	Oneonta, N. Y	Oneonta Electric Light Co	650
41.	Ouray, Col	Ouray Electric Light Co	650
42.	Parkersburg, W. Va	Parkersburg Electric Light & Power Co	1,950
43.	Peekskill, N. Y	Peekskill Electric Light & Power Co	1,300
44.	Philadelphia, Pa	Keystone Light & Power Co	1,950
45.	Pittsfield, Mass	Pittsfield Illuminating Co	1,950
46.	Pittsburgh (S. S.), Pa	Allegheny County Light Co	3,000
47.	Pittsburgh (E. E.), Pa	East End Electric Light Co	5,200
48	Pittsburgh (Virgin A.), Pa	Allegheny County Light Co	10,200
49.	Plainfield, N. J	The Plainfield Electric Light Co	2,600
50.	Port Huron, Mich	Excelsior Electric Co	650
51.	Portland, Me	Consolidated Electric Light Co	650
52.	Richmond, Va	Old Dominion Electric Light & Power Co.	650
53.	Salina, Kans	Salina Gas & Electric Light Co	650
54.	San Antonio, Texas	Electric Light & Power Co	650
55.	Savannah, Ga	Brush Electric Light & Power Co	1,950
56.	Seward, Neb	Seward Electric Light & Power Co	650
57.	Schenectady, N. Y	Westinghouse Illuminating Co	2,600
58	Sheffield, Ala	Sheffield Land, Iron and Coal Co	650
59.	Springfield, Mass	United Electric Light Co	2,600
60.	Springfield, Ohio	Champion Electric Light Co	1,950
61.	Stapleton, N. Y	Richmond Light, Heat & Power Co., L'td.	2,600
62.	Steubenville, Ohio	Electric Light & Power Co	650
63.	Stillwater, Minn	Stillwater Gas and Electric Light Co	650
64.	St. Cloud, Minn	The St. Cloud Gas and Electric Light Co.	650
65.	St. Louis, Mo	St. Louis West. Elec. Light & Power Co	2,600
66.	Tampa, Fla	Tampa Electric Co	650
67.	Torrington, Conn	The Torrington Electric Light Co	1,300
68.	Trenton, N. J	People's Electric Light Co	5,200
69.	Truro, N. S	Truro Electric Light Co	650
70.	Tyrone, Pa	Home Electric Light & Steam Heating Co.	950
71.	Wheeling, W. Va	The Wheeling Electrical Co	1,300
72.	York, Pa	York Electric Co	650

Mr. D. L. Davis has made a contract to light the town of Salem, Ohio, with 55 arc lamps of 1,200 c. p. for five years.

The New Albany Electric Power, Heat and Light Co. will establish a plant at New Albany, Ind.

The Rome Gas Light Co. will build an electric light plant at Rome, Ga.

The Oval Wood Dish Co. will erect an electric light plant at Mancelona, Mich.

The Birmingham Safe and Lock Co. will erect an electric light plant in connection with their works at East Avondale, Ala.

The Westinghouse plant at Oneonta, N. Y., is nearly completed, and will soon be in operation.

Foreign.

Germany.—THE FAILURE OF THE BOILERS AT THE VIENNA OPERA.—After the failure of the large electric light installation at the Vienna Opera House about a month ago, many conflicting reports as to the cause of the failure were circulated. All doubts on this point are removed by the following explanation from Messrs. Crompton & Co., and from which it appears that the interruption was due to the failure of the boilers used at the central station:—

Six steel boilers of 140 h. p. each were made for Messrs. Crompton & Co., by the Witcowitz Iron Co. in Moravia. Messrs. Crompton specified that the material used should be the best mild steel ordinarily used for boiler making. From the very first, however, the steel actually used began to give trouble; one of the plates in the water leg cracked under cold water pressure when it was tested, before steam was got up, and two other boilers failed within 48 hours of starting work. These defects admitted of temporary repairs; meanwhile work was carried on with the other three boilers. After about 12 week's work, however, similar cracks began to show themselves in the main shell of the boilers, which were then considered dangerous, and the work was stopped by order of an imperial commission. The cracking is one of those instances which so often occur with steel boilers We may instance that of the Czar's yacht, the "Livadia," which at the time excited great interest among marine engineers. The cracks in nearly all cases appeared when the boilers were cooled down and opened up for cleaning purposes. The steel used was Bessemer, produced by the basic process. The whole of the six boilers were got out from the underground boiler house, and two large sized locomotive boilers that happened to be available were got into position, and steam got up within nine days of the order to stop the defective boilers. The opera was lighted on the tenth day. The whole of the rest of the machinery was found to be in perfect order, the accumulators not having suffered in the least. With the exception of this one failure of the boilers, there has been no hitch whatever in the running of this large installation of 6,000 lights since the commencement.

Spain.—The largest independent electric light installation in Spain will be that of the Royal Italian Opera House, which is being carried out by the Schuckert company. There will be about 1,500 glow lamps, and a dozen Krizik arcs.

The town of Albacete, which has a population of about 20,000, and which has hitherto been lighted by oil, is adopting the electric light for private and public lighting, 16 c. p. glow lamps being employed. The installation will be ready in a few weeks.

The municipality of Bilbao, which has some surplus engine-power at their water works, intends to utilize it for lighting the principal thoroughfare of the town by means of 82 arc lights. Schuckert dynamos will be used.

M. Edward P. Thompson, of New York, was appointed some months ago consulting electrician of the Compania del Tranvia de Bilbao a Santurce, which has decided to substitute electricity for animal power upon its road of ten miles, at present running cars at intervals of twenty minutes. Having thoroughly investigated the leading systems in the United States, Mr. Thompson made a full report with estimates, upon request of Mr. Arias, the general manager, recommending a well-known American electric railway company, and naming others as in his opinion, worthy of attention. Mr. Thompson has been notified that a decision upon the proposition submitted by him to the Spanish company will be made Jan. 15th.

Switzerland.—The municipality of Geneva is considering a scheme for utilizing the motive power of the Rhone. A report on the subject has just been published, together with a series of resolutions for certain credits to provide for the extension of the distribution of power, to supply electric light to the theatre, and to meet the expenses incurred in the construction of sewage collecting works. Already, by means of turbines and pumps, the municipality not only distributes water throughout its own domain, but also to 15 neighboring communities. In addition, by means of 175 motors, it supplies power in quantities varying from half a horse to 70 h. p., to 145 manufacturers or artisans in their own establishments, homes or workshops, within a circle having a radius of not less than a mile-and-a-quarter from the central station. Hitherto the method of hydraulic transmission has been adopted. But in considering whether it would be best to supply hydraulic power to the theatre for conversion into electricity there, or to supply the electricity direct from the source of the power, the council has decided to combine a system of electrical transmission with its hydraulic system, because it is found that in the case of many workshops—such as those of the clock and watch makers—situated in the upper stories of buildings, as well as in the case of the theatre, there will be a saving of power by the electrical method.

ELECTRIC STREET RAILWAYS IN AMERICA.

Now in Operation.

ABBREVIATIONS.—**mi.**, miles of single track; **g.**, gauge; **lb.**, pounds rail per yard; **m.**, electric motors; **c.**, cars; **m. c.**, motor-cars; **h. p.**, horse-power; **T.**, T-rail. Name of electric system used is in SMALL CAPITALS.

Woonsocket, R. I.—Woonsocket, St. Ry.—*Pr.*, Horace H. Jenckes; *Sec.* and *Eng.*, Willard Kent; 3.5 mi.; g. 4-8½; 30 and 50 lb. T; 9 m. c.; sta. 1,000 h. p.; ovehead cond. BENTLEY-KNIGHT.

Constructing or Under Contract.

Ansonia, Conn.—Derby Horse Ry. Co.—*Pr.* Jno. B. Wallace; *Sec.* and *Treas.* Wm. J. Clarke; *Supt.* Jas. D. Kennedy; 4 mi.; g. 4-8½; 45 lb.; 9 c.; 4 m.; sta. —— h. p.; overhead cond. VAN DEPOELE.

Attleboro, Mass.—Att., N. Attleboro & Wrentham St. Ry. Co.—6 mi.; g. 4-8½; —— lb.; —— c.; —— m.; sta. —— h. p.; overhead cond. SPRAGUE.

Buffalo, N. Y.—Citizen's Elect. Ry. Co.—*Pr.*, A. P. Wright; *Sec.*, F. F. Fargo.

Carbondale, Pa.—Carbondale & Jermyn Elect. St. Ry.—*Pr.* John W. Aitken, *Sec.* and *Treas.*, J. E. Burr; 5 mi.; g. 4-8½; 25 and 57 lb.; overhead cond. SPRAGUE.

Cincinnati, O.—Mt. Adams and Eden Park Inclined Ry. Co.—*Pr.*, Geo. B. Kerper. DAFT.

Dayton, O.—White Line St. R. R. Co.—*Pr.* John A. McMahon; *Sec.* Chas. D. Iddings; *Treas.* Michael A. Nipgen; 8.5 mi.; g. 4-8½; 38 lb.; 16 c.; 8 m. c.; sta. 240 h. p.; overhead and conduit cond. VAN DEPOELE.

Easton, Pa.—Lafayette Traction Co.—*Pr.* J. Marshall Young; *Sec.* and *Treas.*, D. W. Nevin; 1 mi.; g. 5-2½; 35 and 56 lb.; 2 m. c.; overhead cond. DAFT.

Harrisburg, Pa.—East Harrisburg Pass. Ry. Co.—4.5 mi.; 6 m. c.; overhead cond. SPRAGUE.

Ithaca, N. Y.—Ithaca St. Ry. Co.—*Pr.*, Chas. D. Haines; *Sec.* F. H. Skeele; 1.5 mi.; g. 4-8½; 25 lb. T.; 2 m. c.; sta. 50 h. p.; overhead cond. DAFT.

Newton, Mass.—Newton St. Ry. Co.—*Pr.*, H. B. Parker; *V. P.*, Joseph W. Stover; *Sec.* and *Treas.*, H. C. Pratt (office, Newtonville, Mass); 6 mi.; g. 4-8½; 52 lb.

New York, N. Y.—N. Y. & Harlem (Fourth Avenue) R. R. Co.—*Pr.*, C. Vanderbilt; *Sec.* and *Treas.*. E. V. W. Rossiter; *Supt.*, Alfred Skitt; 18½ mi.; g. 4-8½; 60 and 75 lb.; 10 m. c.; storage bats. JULIEN.

New York, N. Y.—North & East River Ry. Co.—*Pr.*, W. W. Laman; 1 mi.; g. 4-8½; conduit conductor. BENTLEY-KNIGHT.

Omaha, Neb.—Omaha Motor Ry. Co.—*Pr.*, Dr. S. D. Mercer; *Sec.*, J. T. Hertzman; *Treas.*, S. S. Curtis; 5 mi.; g. 4-8½; 56 lb.; 20 m. c.; sta. 250 h. p.; overhead cond. VAN DEPOELE.

Ontario, Cal.—Ontario & San Antonio Heights Ry. Co.—*Pr.*, Chas. Frankish; *Sec.* and *Treas.*, D. McFarland; 8 mi.; g. 4-8½; 34 lb.; 4 c.; 3 m.; overhead cond. DAFT.

Richmond, Va.—Richmond City Ry. Co.—*Pr.*, J. L. Schoolcraft; *Treas.*, Walter Kidd; *Supt.*, Chas. Selden; 13 mi.; g. 4-8½; 45 lb.; 40 m. c.; overhead cond. SPRAGUE.

San Jose, Cal.—San Jose Motor Co.—*Pr.*, J. W. Rea.

Scranton, Pa.—The Nayaug Crosstown R. R. Co.—*Pr.*, G. Clark; *Sec.*, T. C. Snow; *Treas.*, B. E. Leonard; 5 mi.; 4-8½; overhead cond. VAN DEPOELE.

South St. Paul, Minn.—So. St. Paul Rapid Transit Co.—*Pr.*, A. E. Clark; *Sec.* and *G. M.*, J. H. Lawrence; 8 mi. (Enos elevated railway); 40 and 56 lb.; 10 m. c.; track conductors. DAFT.

Syracuse, N. Y.—Third Ward Ry. Co.—*Pr.*, Wm. B. Cogswell; *Sec.* and *Treas.*, W. S. Wales; 3.25 mi.; g. 4-8½; overhead cond. DAFT.

Wheeling, W. Va.—Wheeling Ry. Co.—*Pr.*, Jno. Spiedel; *Sec.*, Jno. M. Sweeney; 5.25 mi.; g. 5-2; 45 lb.; 12 m. c.; sta. 240 h. p.; overhead cond.; VAN DEPOELE.

Wilkesbarre, Pa.—Wilkesbarre & Suburban St. Ry. Co.—7 mi.; g. 5-2; 50 lb.; 2 m. c.; overhead cond. SPRAGUE.

Worcester, Mass.—Worc. & Shrewsbury—(To be changed from steam to electricity); 2.7 mi.; g. 3; overhead cond. DAFT.

Notes.

THE eight-wheeled accumulator electric car which has been built in Philadelphia by Wm. Wharton, Jr., is undergoing a thorough experimental trial with very satisfactory results. It is propelled by two Reckenzaun motors, and 116 cells of Electrical Accumulator Co.'s battery. A recent run reported, with one charge of the cells, was 63 miles and 211 feet in eight hours, traversing 331 curves of 33 feet radius, 662 curves of 50 feet radius, and five miles of grades of 5.8 per cent., a splendid piece of work. Mr. Wharton says that the weight of the Reckenzaun motor per horse-power developed is only about one-third that of the Sprague railway motor and one-sixth that of the Van Depoele motor. He also claims that its percentage of efficiency is much higher than that of the Sprague motor.

GREAT complaint is made in Richmond, Va., respecting the uncouth appearance of the overhead structure for carrying the conductors for the new street railway. It ought to be possible to avoid this objection.

THE *Street Railway Gazette* says that Charles Green, president [illegible] People's Railway Co., and Christian Peper, of the St. [illegible] R. Co., have been "converted" to electricity.

THE LANE & BODLEY CO., of Cincinnati, have supplied the steam plant for the new Van Depoele electric street railway, now building in Dayton, Ohio. Three 80 h. p. dynamo will be driven by clutch-pulleys from a line shaft.

THE KANSAS CITY ELECTRIC RAILWAY CO., operating under Henry's system, made an assignment, Dec. 12, to Evan A. Fursell, for the benefit of its creditors. The assets are valued at $12,000, liabilities not stated. The company has spent too much money in experimenting.

THE new Observatory Hill electric railway in Allegheny, Pa., is thoroughly well built, and as it runs through a charming suburban region, heretofore very difficult of access, it is likely to prove a highly profitable enterprise.

THE THOMSON-HOUSTON CO., of Lynn, have gone into street car motor work, and their machinery is reported as doing excellent service. The Bentley-Knight company are using them on their cars.

COL. E. H. HEWINS, of the New England Weston Co., of Boston, has been exhibiting a car fitted with a 10 h. p. Weston motor, and 120 cells of Julien accumulators. The car has made several runs over the West End company's tracks in Cambridge and Boston, with apparently satisfactory results.

THE DENVER TRAMWAY CO. is about to extend its plant, and has ordered another 100 h. p. generator.

TWO of the model electric street railways of the country are the Appleton (Wis.), and the Scranton (Pa.) lines, both constructed by the Van Depoele company. They have heavy and well-laid steel tracks, elegant cars, and well designed machinery. Both these lines are deservedly popular with the public and it is almost superfluous to add, are making money rapidly.

THE electric street railway put in at Mansfield, Ohio, by the Daft company, is doing a good business and is giving excellent satisfaction.

THE new electric railway at Columbus, Ohio, is to be constructed on the Short system, with a sub-surface conductor. The Brush company, of Cleveland, are supplying the electric machinery.

MANUFACTURING AND TRADE NOTES.

THE GEO. F. CARD MANUFACTURING Co., Cincinnati, Ohio, are prepared to supply electric motors of small and moderate size for use on electric light circuits or with batteries. Their handsome catalogue contains a description of the distinctive features of their motors, with illustrations, setting forth several features of interest.

THE ELECTRIC GAS LIGHTING Co., of Boston, are having a large demand for their new "single magnet" ratchet burner. It is extremely simple in construction, and direct in action, with very small liability to disarrangement. It is highly commended for use in houses, banks, stores, etc. The manufacturers regard its principles of construction as affording the only safe and sure method of turning gas on and off, and igniting it simultaneously by electricity. The company are also manufacturers and wholesale dealers in all styles of electric goods, lighting apparatus and electrical appliances in general.

THE WATERHOUSE ELECTRIC AND MANUFACTURING Co., Hartford, Ct., have doubled their capacity for the production of electric light apparatus, and are very busy on orders.

Among the recent installations and orders received for arc lights are The Waterhouse Electric Co., Baltimore, Md., 500; The Newark Schuyler Electric Light Co., Newark, N. J., increase 100; The People's Electric Light and Power Co., Wellsville, Ohio, 60; The Fredericton Electric Light Co., Fredericton, N. B., 66; Fresno Gas Co., Fresno, Cal., increase 30; W. C. Clark, San Francisco, Cal., 75; H. N. Green, Cadillac, Mich., 70; Taft, Weeden & Co., Providence, R. I., 33; Slater Cotton Co., Pawtucket, R. I., 30; E. Jencke's Mfg. Co., Pawtucket, R. I., 83; Washington Gas Co., Washington, Ind., 30; Jarecke Mfg. Co., Erie, Pa., 33; The Billings & Spencer Co., Hartford, Ct., 25; Forest Fibre Co., Berlin Falls, N. H., 30; Messrs. R. & H. Simon, Union Hill, N. J., 70.

MESSRS. SHAW & GEARY, of Philadelphia, have established a going and growing business in the manufacture of electrical appliances. They give particular attention to gas lighting, annunciator, and signal apparatus generally. Mr. Geary is a mechanic of a high order, and has had large experience in electro-mechanical work in prominent establishments. The catalogue of the firm exhibits several specialties of interest to the purchasers of electrical supplies.

MESSRS. JAMES W. QUEEN & Co., of Philadelphia, have added to their large list of scientific apparatus, the new electrical balances of Sir William Thomson. These instruments are manufactured by the celebrated James White, of Glasgow, and Messrs. Queen & Co. have been made sole agents for their [illegible] in the United States. The firm has for many years given spe[illegible]tention to supplying high class physical apparatus for educational, laboratory and practical use; and they evince their intention to keep abreast with progress in arranging so promptly to supply American electricians with Sir William Thomson's latest contribution to their metrical apparatus.

THE WATERHOUSE ELECTRIC AND MANUFACTURING Co., of Hartford, Conn., have been awarded a gold medal for their system of arc lighting on account of tests made of their apparatus at the Mechanic's Fair, Boston, just closed. The judges report is highly commendatory to the Waterhouse system, and special mention is made of the Waterhouse regulator. The Waterhouse system is being rapidly introduced. The company have doubled their capacity recently, and are installing many plants.

THE ANNUAL MEETING of the stockholders of the Westinghouse Electric Co., of Pittsburgh, was held in the offices of the company, in that city, on Friday, Nov. 25. The reports submitted to the stockholders showed that the affairs of the company were in a satisfactory condition, and the outlook for the coming year is exceedingly bright. Since April 1, 80 plants have been supplied, with an aggregate of over 108,000 lights, and there are contracts in hand for almost as many more. The company now employ about 1,000 persons, and when the new buildings are completed and occupied, by Jan. 1, next, this number will be almost doubled. The earnings of the company thus far in 1887 have been in excess of 10 per cent. on the capital of $5,000,000, and are steadily increasing.

THE ABENDROTH & ROOT MANUFACTURING Co., 28 Cliff street, N. Y., have recently closed contracts for Root's Sectional Safety Boilers, with the Edison Illuminating Co. of Detroit, Mich., First Cincinnati Edison Illuminating Co., Cincinnati, Ohio, Jersey City Electric Light Co., Jersey City, Brush Electric Light Co., Louisville, Ky., Columbus Edison Electric Light Co., Columbus, Ohio, and the Edison Electric Light and Power Co., St. Paul, Minn.

THE AMERICAN INDURATED FIBRE Co., Mechanicsville, N. Y., are finding demand for their patent wood fibre pipe, for gas and water distribution, and for underground electric wires. The pipe is manufactured from long wood fibre, specially prepared by separation of the wood and fibres, and thoroughly washed and freed from saps and gums; while in this pulpy state it is carried into forms, and, by enormous hydraulic pressure, is shaped into pipe. The pipe, after being thoroughly saturated with a special chemical mixture, is baked in a very high temperature. It is said to become strong, hard, and impervious to acids and moisture, and absolutely water-proof and proof against decay, and practically indestructible.

THE OKONITE Co. have issued a new circular and price-list for 1888. The Okonite insulation has become well and favorably known among electricians. The products of the company, as set forth in their catalogue, cover a wide range of uses—from submarine cables to single wires as small as No. 24 B. W. G. Particular attention is given to supplying electric light conductors.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions,* 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From Nov. 22d to Dec. 13th., 1887 (inclusive).

Alarms and Signals:—*Electrical Indicator for Weighing Scales*, J. E. Tarbox, 374,013, Nov. 29. *Electric Temperature Indicator*, J. C. Boyle, 374,581, Dec. 13.

Conductors, Insulators, Supports and Systems:—*Insulating Joint or Pipe Coupling*, E. F. Gennert, 873,452, Nov. 22. *Manufacture of Telegraph and Other Poles or Posts*, D. Wilson, 374,103, Nov. 29. *Apparatus for Covering Wire with Soft Metal*, J. C. Appleby, 374,164, and 374,166. *Conduit for Cable or Electric Railways*, W. Nier, 374,315. *Underground Conduit for Electrical Conductors*, G. W. Cook, 374,348. *Underground System for Electric Wires*, J. P. Davis, 374,458, Dec. 6. *Conduit for Electric Conductors*, E. E. Greene, 374,738, G. D. Holt, 374,792, Dec. 13.

Clocks:—*Electrical Horometer*, B. M. Hammond, 373,975, Nov. 29.

Distribution:—*System of Electric Distribution*, M. Waddell, 374,381, Dec. 6.

Dynamos and Motors:—*Dynamo Electric Machines*, T. A. Edison, 373,584. *Prevention of Sparking in Electric Motors and Generators*, D. Highen, 373,739, Nov. 22. *Regulation for Electric Generators*, R. P. Sellon and W. M. Mordey, 373,859. *Winding Armatures of Dynamo-Electric Machines*, C. E. Scribner, 373,948. *Commutator-Connection for Dynamo-Electric Machines*, J. W. Easton, 373,971, Nov. 29. *Electric Motor or Dynamo-Electric Machine*, F. J. Patten, 374,621. *Armature*, H. B. Slater, 374,711. *Dynamo-Armature*, E. N. Bliss, 374,728. *Electric Generator and Motor*, A. F. Congdon, 374,778. *Dynamo-Electric Machine*, G. Westinghouse, Jr., H. M. Byllesby, O. B. Shallenberger, A. Schmid, and B. Hartley, 374,858. *Electric Motor*, W. Hochhausen, 374,871. *Apparatus for Reversing and Controlling Electric Motors and Other Translating Devices*, same, 374,872. *Regulation of Electric Motors*, W. Stanley, Jr., 374,910, Dec. 13.

Galvanic Batteries:—*Galvanic Battery*, H. Brewer, 373,435, Nov. 22, H. E. Waite, 374,329, F. J. Crouch, 374,456, Dec. 6, J. Serson, 374,631, J. Freeman, 374,668, J. A. Barrett, 374,863. *Electric Battery*, same, 374,862, Dec. 13.

Ignition:—*Electric Gas-Lighter*, J. B. Entz, 374,528, Dec. 6.

Lamps and Appurtenances:—*Electric Arc Lamp*, G. A. Wiese, 373,761, Nov. 22. *Application of Accumulators to Electric Lighting*, T. P. Conant, 373,883. *Electric Arc Lamp*, C. A. Homans, 373,984. *Arc Light*, C. B. Noble, 374,129, Nov. 29. *Incandescent Electric Lamp*, M. Wheeler, 374,224, Dec. 6. *Method of Testing Electric Lamp Globes*, C. F. Reinmann, 374,850, Dec. 13. [illegible] *for Measuring Electric Currents*, H. Aron, 374,860, and 374,[illegible]

Medical:—*Electro Medical Apparatus*, J. S. Muir, 374,7[illegible], Dec. 13.

Miscellaneous:—*Feed-Water Heater*, C. W. Fowler, 373,520. *Electric Coupling*, G. W. Taylor, 373,759, Nov. 22. *Automatic Circuit-Opener*, J. P. Tirrell, 374,017. *Electric Door-Opener*, A. C. Woehrle, 374,028. *Circuit-Closer*, B. R. Bosworth, 374,436. *Electric Temperature Regulator*. W. S. Johnson, 374,072. *Eectric Organ Action*, H. L. Roosevelt, 374,088. *Paper Cylinder for Graphophonic Records*, C. S. Tainter, 374,133, Nov. 29. *Apparatus for Converting Heat Energy into Electrical Energy*, W. E. Case, 374,173. *Electrical Dental Engine*, G. W. Whitefield, 374,225. *Electric Governor*, W. H. Reynolds, 374,374. *Regulator for Electric Currents*, S. D. Field, 374,404. *Regulation of Electric Generators*, D. Higham, 374,406. *Coin-Operated Induction Coil*, W. R. Pope, 374,495, Dec. 6. *Revolving Electric Hammer Tool*, W. G. A. Bonwill, 374,580. *Electric Fuse*, K. J. Sundstrom, 374,640. *Circuit-Breaker*, C. B. Bosworth, 374,652. *Safety Strip for Electric Circuits*, P. Lange and O. B. Shallenberger, 374,842. *Electric Coupling Device*, P. Lange, 374,843. *Electro-Mechanical Movement*, H. Van Hoevenbergh, 374,883. *Wire-Splicer*, W. F. Batten, 374,650, Dec. 13.

Railways and Appliances:—*Electric Railway*, E. M. Bentley, 374,736. *Rail-Connection for Electric Railroads*, E. L. Orcutt, 374,199, Dec. 6. *Railway-Switch*, S. C. C. Currie, 374,733, Dec. 13. *Contact-Brush*, E. L. Orcutt, 374,198, Dec. 6.

Storage Batteries:—*Automatic Circuit-Closer for Secondary Batteries*, W. W. Griscom, 374,673, Dec. 13.

Telegraphs:—*Printing Telegraph*, C. J. Wiley, 373,508, Nov. 22. *Induction Telegraph System*, G. T. Woods, 373,915. *Telegraph-Pole Protector*, H. P. Copeland, 373,925. *Telegraphy*, P. B. Delany, 373,967, 373,968. *Telegraph Instrument*, C. G. Burke, 374,038, Nov. 29. *Telegraph Transmitter*, A. Bixby, 374,390. *Printing Telegraph*, same, 374,444, Dec. 6.

Telephones, Systems and Apparatus:—*Telephone Apparatus*, I. H. Farnham, 373,519. *Device for Attaching Tablets to Telephone*, H. H. Butler, 373,767, Nov. 22. *Mechanical Telephone*, J. P. Sunderland, 373,862, *Telephone Call-Box*, C. E. Scribner, 373,910, Nov. 29. *Transmitter*, R. W. Whitney and F. Pultz, 374,439, Dec. 6. *Multiple-Switch-Board Test-Circuit*, C. E. Scribner, 374,907, Dec. 13.

THE

ELECTRICAL ENGINEER.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed*, EDITOR OF THE ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

NEW YORK, FEBRUARY, 1888.

We are pleased to renew our announcement of last year that by arrangement with the ELECTRICAL WORLD, *we are able to offer that excellent weekly journal in conjunction with* THE ELECTRICAL ENGINEER, *for one year to new subscribers for* $5.00. *To those of our present subscribers who desire it we will supply the* ELECTRICAL WORLD *one year for* $2.50

MR. EDISON ON PATENT PROTECTION.

THE unthinking and unintelligent members of the body politic who are clamoring for the overthrow of our patent law, under the wholly mistaken impression that the consummation of their design would in some unexplained way, aid in the suppression of their pet bugaboo, "monopoly," have received a notable recruit to their ranks in the person of one of the principal beneficiaries of the system which it is proposed to destroy. Ordinarily, the right of a private person to the unmolested enjoyment of his own opinions in respect to this or any other subject is not to be questioned, but when an inventor occupying so prominent a position before the public as Mr. Edison, appears on record as an exponent of the opinions attributed to him in the published interview which we reprint in another column, his action ought not to pass without comment. Mr. Edison is reported as saying :—

The present law is a constant temptation to rascals, and virtually offers a premium upon rascality; under it the infringer of a patent is not interfered with until the real owner can show that he has the monopoly of the device in question. This process may take years, during which the infringer who has money and audacity enough to seize another man's invention can go on and perhaps wear the rightful owner's life out by litigation and annoyance. I have had so much of this sort of thing within the last five years that I have almost made up my mind never to take out another patent until the law is changed. The burden of proof is now put entirely upon the man who holds the patent, instead of upon the man who wishes to infringe it, whereas it ought to be all the other way.

An old proverb bids one to speak well of the bridge that has carried him safely across the stream. It is not many years since Mr. Edison was earning, by diligence and industry, a modest stipend of some three dollars per diem as a telegraph operator, and it is but just to say that he was accounted a very skillful one, and well worth the money. To-day he occupies the finest estate in the vicinity of the metropolis, and if he is not twice a millionaire, it can be for no other reason than that like too many of the rest of us, he has found it less easy to keep money than it is to get it. We venture to assert, that had it not been for the patent law, which he now decries, Mr. Edison would, in all human probability have been "pounding brass" as the phrase is, at this moment, although it is doubtful if in the absence of the inventions, which the patent law has fostered, anybody could afford to pay him more than $1.25 per day. Who would have given him a dollar in exchange for his quadruplex and automatic telegraphs, and his electric light inventions, had it not been for the patent law? Would he not have been obliged to content himself with the modest wage earned by daily industry? He adds, mysteriously :—

I have already found one chemical device which promises to pay me handsomely, and the Patent Office will never hear anything about it; to apply for a patent would simply invite a lot of rogues to share with me, or, what is more likely, to take all the profits.

Every right-minded person will be gratified to learn that the prospects of Polyform, if indeed it be that excellent remedy which is referred to, are so flattering. But to return to the patent law. Mr. Edison complains :—

There is scarcely an invention of importance made within the last generation which has not been disputed upon frivolous grounds, and the inventor put to all sorts of annoyance. In my own case, I am sure that no matter what I may patent, some one will come up as soon as the patent is seen to have any value and show by dozens of witnesses, if necessary, that he is the rightful owner of the invention. If I patent to-morrow a process for making good flour at a cost of two cents a barrel, the publication of my patent would bring out about 10 men who could prove that they did that sort of thing years ago, and that I had no right to a patent.

This is not simply an indictment of the patent law, but of all law whatsoever, and the real root of the trouble obviously lies, not in the statutes, but in that inborn proclivity of the unregenerate human animal which prompts him to appropriate his neighbor's property, and which it is one of the principal functions of the common law to prevent and punish. The patent law merely serves to protect the inventor by declaring that an invention is property, and that it may, therefore, be the subject of larceny.

The federal courts have never to our knowledge, pronounced any patent whatever invalid, because of prior knowledge or prior use by another, except the anticipating invention had been actually embodied in a concrete and operative machine or method, and that fact had been proved beyond a reasonable doubt. That the law is designed to protect, and that it does in fact protect, the real originator, is abundantly shown in the cases of such inventors as Goodyear, Howe, Morse, Bell, Edison, Westinghouse and many others, whose achievements have served to render the annals of American industry illustrious.

The fact is, and it is well to bear it in mind, that the

pre-eminence of the United States, as distinctively a nation of inventors of improved machinery and processes, dates back no further than the patent law of 1836, which is substantially the one now in force, and it is to the fostering care of this wise statute, more than of any other which has ever been enacted by Congress, that this country owes its present prosperity and greatness.

Do not lay rash hands on the patent law. Let the American inventor be protected. *In hoc signo vinces.*

POST-OFFICE TELEGRAPHY.

WHILE it is somewhat unlikely that a bill for the assumption of the telegraph business of the country by the Government will be matured and acted upon by Congress during the present session, the project is again receiving a good deal of attention, both in and out of the National legislature, and will doubtless, at no very distant time, come up for adoption or rejection. Our Washington correspondence describes a number of schemes proposed by members of Congress.

The question was very fully considered at Washington some fourteen years ago at the instance of the Hon. Gardiner G. Hubbard, when a postal telegraph was energetically opposed by the Western Union Telegraph Co. before Congressional committees. The expediency of the measure then before the country received a prolonged and voluminous discussion in the public press; advocates and opponents of the scheme brought forth and spread before the country exhaustive collections of facts, figures and arguments till, it is safe to say, nothing was left undone to enlighten the judgment of legislators and the public. The promoters of the project were vigorous and persistent in the advocacy and prosecution of their plans, but failed of success.

In current and future agitation of the subject it seems probable that abstract or constitutional objections will count for little, and that discussion will be concentrated chiefly upon economic considerations, or in other words, the expediency of a post-office telegraph system for the service of the public.

Whether or no the pendency of this question and the certainty that it would be brought forward from time to time have served to stimulate the Western Union Telegraph Company in improving and cheapening their service, the receipts of that company per message have been reduced, since 1874, from 56 cents to 30 cents (say 46 per cent.), whilst their facilities—miles of poles and wire and number of offices—have been much more than doubled. When, before the Senate Post-Office Committee, January 20th, Dr. Norvin Green, president of the Western Union Company, distinctly pledged that corporation not to increase the rates of the past year, and promised further reductions during the current year.

COPPER.

THE extraordinary advance in the price of copper which has taken place within the past few months, still continues, and cannot fail to affect electrical interests seriously, if present prices are maintained for any considerable period. While it is true that the present figure of 16 to 18 cents is not very high compared with the quotations between 1865 and 1875, which ranged from 20 to 30 cents, yet it is an advance of 60 to 80 per cent. on the lowest figure reached in 1887, and entering so largely as it does, into the entire cost of an electric lighting or power plant, is certain to make a very material difference in the price which the purchaser will be obliged to pay. The entire movement is apparently due to the operations of a French syndicate, which started out some months since to "corner" the copper market of the world. The fire in the Calumet and Hecla mine, the principal source of the American copper supply, occurred just in time to aid the projectors of this scheme in its successful consummation.

Everything indicates that the price of copper will be forced higher and higher, until, in the slang of the exchanges, "the bottom drops out," when in all probability the price will fall with startling rapidity to a point in the neighborhood of 12 cents. Meantime manufacturers of electrical copper goods are pursuing a cautious and conservative policy, and buying only as fast as needed, so that, by means of frequent revisions of their discount lists, they may be able to avoid any serious losses. The present movement appears to be purely speculative, and it is not probable that the present high prices can be maintained for any great length of time.

If the advance in the price of copper prove to be more than temporary in its effect, one of its incidental results will be to handicap seriously the low potential systems of electrical distribution, in their efforts to compete commercially with the high potential systems of more recent introduction.

AMERICAN readers of English electrical journals have doubtless observed with some surprise the large measure of attention that has been secured in Great Britain during the past year or two by exploiters of various primary batteries for electric lighting; attention not only of electricians but of investors as well. There is no evidence of any substantial successes in the use of primary batteries for the supply of current in large quantities; nor do we believe that any success has been looked for by well-informed electrical engineers. One or two efforts in the same direction have been made here, but they attracted relatively small attention in electrical circles, and the enterprises founded upon them seem to have made but little headway. Without some radical and revolutionary discovery in chemistry there appears no reason to expect the cost and inconvenience of primary batteries to be brought within practicable limits for lighting or power currents.

WE have been favored with a copy of the "Report of the Commission to Investigate and Report the Most Humane and Practical Method of Carrying into Effect the Sentence of Death in Capital Cases," presented to the New York Legislature, January 1st. The gist of the report is contained in the recommendation that Section 505 of the Code of Criminal Procedure be amended to read as follows:

> § 505. The punishment of death must, in every case, be inflicted by causing to pass through the body of the convict a current of electricity of sufficient intensity to cause death, and the application of such current must be continued until such convict is dead.

It is difficult to imagine any reasonable objection to the

proposed substitution of the dynamo for the gallows. Further recommendations of the Commission in respect to the time, place and privacy of executions are clearly in the interest of public decency and order.

It is not easy to comprehend why the Commission should have seen fit to precede their suggestions by an historical sketch of all modes of capital punishment, ancient and modern, including horrors that would better be left to the ken of special students only.

The index of current electrical literature, dating from October, begun by the Institute of Electrical Engineers in the monthly volumes of transactions for December and January, will be highly appreciated by all who have occasion to consult such literature. The work has been very carefully done, and greatly enhances the value of the published volumes of the Institute. It has been suggested that it would add to the usefulness of the index to print it on only one side of the pages, thus enabling those readers who make card catalogues to do so conveniently without copying. There would be no objection, in such cases to cutting up the monthly installment of the index, as it is, we believe, intended to re-print the whole in each yearly volume.

This index is but another example of the devotion of the President and Secretary to the work of the Institute. They have given their time and service without stint for the promotion of its interests. It is very gratifying to observe the large growth of the society during the current year, not only in numbers, but in character and influence.

The National Electric Light Association will hold its Annual Meeting at Pittsburgh, February 21–23. The importance of many recent developments in the art and business of electric lighting, together with the central location of the place of meeting, will doubtless secure a large attendance of members and others. Pittsburgh affords an excellent opportunity for the inspection of alternating current plants in operation, there being several such in the immediate vicinity. It seems to be understood that the measures initiated by the Association for obtaining from Congress the appointment of a Commission to revise the patent system will come up for further discussion and final action at the Pittsburgh meeting.

Mr. C. A. Brown's paper on Revision of the patent law, read before the Chicago Electric Club, January 16, and which we print elsewhere in this issue, offers very weighty reasons against the project of the National Electric Light Association. Mr. Brown looks at the matter from the point of view of a careful student of legal questions as well as of a man of business intimately acquainted with the relations of patents to manufacturing enterprises. His consideration of the proposed creation of a commission to overhaul the entire patent system has led him to conclusions much in accord with the views expressed by the Electrical Engineer in December. Mr. Brown sees good reason for apprehension lest an attempt at a general revision by a commission may lead to results quite the reverse of those desired by the advocates of reform in the patent system.

There can be little doubt that, with very few exceptions, electrical manufacturing and construction companies and firms still carry on their work with insufficient attention to scientific and technical, not to say economical principles. There seems to exist in many quarters a deep-rooted aversion to the recognition and employment of highly trained technical talent in the design and construction of electrical plants for light or power. The American instinct to trust to gumption and cuteness prevails largely in electrical circles. The attitude of some enterprising "practical" manufacturing and construction concerns towards trained electrical engineering skill, reminds us of the convocation of local magnates in a frontier town of considerable size, that had grown up in a few months, and who explained the absence of a church to an eastern capitalist, conferring with them about the further development of the business of the place, by saying that "they had thought of starting a church" but after due deliberation had concluded "it would look too dudish."

The charges of the Electrical Engineer for editorial advertising are placed at so high a figure that we seldom have an opportunity to earn an honest penny thereby. In the present instance we look for no remuneration beyond the sense of rendering service by announcing the discovery of a unique and valuable servitor awaiting the call of those who perhaps know him not. An electrical corporation permits us to copy the following communication, received by them in the course of business:—

"TO THE MOST CLEAR HEADED MAN" IN

"The__________ __________Electric__________ Co.'

Every man has his forte.
Napoleon conquered Europe.
Morse invented the Telegraph.
Bell " " Telephone.
Edison " " Electric Light.

We write circulars, books, pamphlets, advertisements. It is a great *Art* to write them epigrammatically, graphically, originally, uniquely. Our prices are *cheap* but not *low.*

Invest a postal and get our estimates.

Please *paste* this in your city directory. Better make one giant stroke than a thousand feeble attempts.

Yours, faithfully,

Should any of our readers who distrust their own ability to set forth adequately the pre-eminent merits of their wares or undertakings desire the assistance of this ready-writer, we shall be pleased to use our best efforts to obtain permission to furnish his name and address.

In the comments upon electrical litigation in the editorial columns of The Electrical Engineer for January, an error was made in the paragraph referring to the suit of the Thomson-Houston company against the American company for infringement of patent. The patent upon which the suit is based is No. 238,315, to Thomson and Houston as joint inventors, and not, as stated in the article referred to, "Professor Thomson's patent."

ARTICLES.

DISCUSSION OF THE PRECISION OF MEASUREMENTS.[1]

BY SILAS W. HOLMAN.

In quantitative measurement of any kind, and more obviously in physical work, but little progress can be made before questions respecting the precision of the results, and of the component measurements which go to make up those results, thrust themselves upon the observer. For simple, direct measurements, it may suffice to state in a few words the process of averaging and of inspecting the concordance of the measurements. These, with proper allusions to instrumental errors and their elimination, would at least readily satisfy the demands of all but quite advanced students. But, in fact, few physical, and almost no electrical measurements are direct, if we except such commercial work as corresponds in grade to the measurement of cloth with a yard-stick. For instance, a student is set to determine the specific electrical resistance of a sample of wire. He has, we will say, to measure the length, weight and resistance of the wire, its temperature, and that of the resistance box by which he measures. The thoughtful student will ask himself at once how closely each of these quantities must be measured, in order that he may get the final result with the desired closeness. He will appreciate, especially if he has previously done physical or chemical work, that not only must all the quantities be measured with some care, but that each will have its own special requirement as to grade of accuracy, which ought to be known in advance of his final observations, and which *must* be complied with if the desired final accuracy is to be reached. Thus in careful work, even when not of a high grade, and in qualitative as well as in quantitative study, it is essential to predetermine the necessary conditions in the component parts of the work; that is to arrange or select the instruments for giving the most favorable conditions for the work, to proportion aright the parts of the instruments, to distribute properly the precision of the component measurements. And finally, less important in reality but ordinarily made more conspicuous, we should know how to form a numerical estimate of the reliability of the final result from the precision and nature of the component measurements which go to make that up.

The lecture course, of which the following pages contain the chief portions of the notes, was arranged with such thoughts as the foregoing in mind. Its direct object is to present to students somewhat advanced in electrical measurements, a systematic method by which such inquiries might be investigated; to illustrate this method by a number of original investigations worked out in detail; and to present some problems for solution. The demands of the course did not render an exhaustive treatment imperative, so that the notes have not always been thrown into the most general form. But it is thought that they contain enough to serve as a basis upon which a competent student may solve any questions of this nature which he may ordinarily meet. The course assumes a knowledge of the differential calculus, and some acquaintance with the theory of probabilities, and the principle of least squares —subjects which in the order of these topics at the Institute precede the present one.

Given the result of an investigation or measurement of any kind, the first inquiry in regard to its quality is, or ought to be, what degree of confidence can be placed in it. In general, of course, the true value is unknown, and the above query can be answered only by statement of the probable accuracy of the result—for which it is necessary to find some numerical measure. It means nothing to the careful worker to be told that a given numerical result is "very accurate," or "quite accurate," etc., because he is aware that these terms have to different persons wholly different meanings. A numerical measure is essential. How can this be found?

It is obvious that an answer may be framed in this way: let the same quantity be measured many times, by many wholly distinct processes, and by many independent observers. The average, or arithmetical mean of all these results will be likely to approach the truth, and to come closer to it as the number increases. For we may assume, with a high probability, that exactly the same sources, magnitudes, and directions of error will not occur uniformly in all the results, but that there will probably be many errors, some +, some —, and of graded magnitudes, which, in the process of averaging, will tend toward the complete canceling of one another. Then the real error of any one of these independent results would be approximately given by its deviation from the average or mean result. It is, of course, very unusual to be able to command such series of measurements; but on that account it remains even more necessary to be ordinarily able to obtain an *estimate* of accuracy, and the method for doing so must therefore be developed.

For clearness, let us agree upon the following use of terms, and review some points concerning the nature of measurement and errors.

Let the term *precision* be used only with reference to the accordance of the individual results of a series; *i. e.*, their agreement among themselves or with the value adopted to represent the series, but without any reference to the possible divergence of the result from the truth.

Let the term *accuracy* be confined in its use to the latter case; *i. e.*, where it is desired to hold under consideration the observed result as a representative of the *true* result, or as differing from it. The *accuracy* of a result would then be under consideration when its *errors* were referred to (*i. e.*, observed minus true values); but in dealing with *deviations* of single results from the mean or representative result or from each other, only the *precision* would be under consideration.

Direct measurements are those made in such a way, or by aid of such instruments, as to obtain directly the quantity sought; *e. g.*, measurements of distance by a scale, of weights with a balance, of resistance with a bridge, etc. The direct readings may or may not require corrections.

Indirect measurements are those where the desired result is not given directly by the measurement, but as the result of some combination of several observed values of different quantities,—in other words, where the result is a function of the observed quantities; *e. g*, measurement of a distance by geodetic triangulation, of current by a tangent galvanometer or electro-dynamometer, of battery electromotive force or resistance by two deflections on a tangent galvanometer, etc.

Quantities subjected to measurement may be either *independent* or *conditioned*. That is, two or any number of quantities may be wholly independent, so that the magnitude of one is in no way predetermined by any relations to the others; or they may be conditioned so that, for instance, the magnitude of two out of three being given, that of the third is thereby predetermined. Thus the current flowing through a given resistance might be anything whatever, according to the potential used, so that measurements of current and of resistance at any instant would be independent. But if the potential difference at the ends of the coil were simultaneously measured, then the three, current, resistance, and potential, would be conditioned by Ohm's law. The numerical values obtained in the measurement of conditioned quantities contain, of course, errors not controlled by these conditions, so that the values fail to fulfill the conditions, and require adjustment.

Every measurement, of whatever sort, is subject to errors. In coarse work it is easy to bring these within the limits allowable; in fine work, difficult or impossible. The sources of error may be regarded as of two classes, determinate and indeterminate.

1. From *Technology Quarterly*.

Determinate sources of error. In any given investigation, a study of the instruments methods, and conditions of observation employed in the light of all accessible knowledge in regard to these will reveal many possible sources of error, whose effects may be determined with greater or less closeness. Corrections may then be applied therefor, or the instruments, processes, and conditions so modified as to eliminate them. Such sources of error would exist in the rate of a clock, in the graduation of a scale or circle, in the weights or beam of a balance, in the shape or adjustment of the coils of a galvanometer, etc. The study of these determinate errors is the most laborious part of an investigation, and is absolutely essential to even coarse work. Its neglect is repeatedly apparent in contradictory, and often useless results of elaborate work. But at the best, the correction and elimination of errors can be seldom more than approximate, and must leave behind residual errors, of greater or less magnitude, which will belong to the class of iudeterminate errors; yet the attempt should always be made to render these residuals so small as at least not to exceed the average of the variable indeterminate errors. A general consideration of the nature of corrections, and of the closeness with which they should be determined, will be given later.

Indeterminate sources of error. Apart from the recognizable and determinate sources of error, there is a large number of unrecognizable, or at least indeterminate sources. To the nature of these, careful study may fail to give any clue. We only know that between successive measurements by the same process and between the results obtained by processes entirely or partly independent, discrepancies are always found. This demonstrates the perpetual existence of these indeterminate disturbing sources. They are thus indeterminate not in magnitude and sign only, but often in nature also. Some, however, are of known origin, but are not determinable on account of their small magnitude or of our inability to sufficiently control or measure their effects.

It is obvious that these indeterminate errors, in some degree, counterbalance each other; but there is always liability in any particular case to a preponderance of a single or resultant disturbing effect, which no process of averaging or combining the separate results can eliminate. Thus there will in general be a residual indeterminate error, which may be, and often is, surprisingly large. Such an error being naturally of a nearly constant amount (often called "a constant error"), would *not* be rendered apparent by the deviations among the single results. Hence the *precision* measure (p. 46), *i. e.*, the measure of concordance of the results, would give no intimation of its existence, and is, therefore, never a true *accuracy* measure. The only hope of a sufficient elimination of indeterminate errors lies in the plan already suggested—of combining *many* results obtained by *many distinct* methods and observers.

Corrections. The process of determining the amount of a correction is in itself, or involves, a subsidiary investigation. It may consist of such an operation as comparing a scale with a standard, of determining the rate of a clock, of computing the effect due to the size and form of galvanometer coils, or to the short length of the mercury column in the exposed stem of a thermometer, etc. Few corrections can be found with absolute accuracy; in most cases the correction is determined by some physical process which will yield results of a desired accuracy, but will itself be subject to sources of error, which, in their turn, must be properly eliminated, and so on. Thus the study of the correction must be carried out under such conditions as to insure that its determinate errors have been so far removed that their residuals, in their turn, may properly be classed among the indeterminate errors. As to how small the precision measure of the correction should be rendered when all recognizable sources of error have been removed, it may here be said that this will be determined by two things,—the precision desired in the main result, and the labor involved in ascertaining the correction.

From this, it is obvious that if it were necessary in an investigation to work out from the beginning every detail of the research, establishing all standards, ascertaining all corrections, developing every process employed, the labor would be enormous—as, indeed it often is. But fortunately the progress of experimental science has provided instruments, processes, methods, and results of known accuracy, which may be appropriated in any desired manner in more complex investigations.

Deviations vs. Errors. What is known of the laws *of error* is purely the result of inference. True values are never absolutely known. Let a_1, a_2, etc., be single observations of a quantity of which the true value is R. Their errors would be $E_1 = a_1 - R$, $E_2 = a_2 - R$, etc., but these cannot be known as R in unknown. Let A be the value chosen as the best representative (*e. g.* arithmetical mean) of the series. Then we know $d_1 = a_1 - A$, $d_2 = a_2 - A$, etc., which may be called the *deviations* of the single results from the best value, however that may be arrived at. The laws of these deviations have been studied for many different series of actual measurements. They are not the same for all cases. The following is, however, the most general case, and that from which the law of "accidental errors" is inferred.

Suppose an *indefinitely large number of equally careful* observations of a quantity made in a great variety of ways, and under widely different conditions: prolonged experience shows that the deviations of the single observations from the mean, in such a series, are distributed according to a definite law, which is approximated to more closely as the number of observations is greater, and which may be represented by an exponential equation. Of this distribution, it may be said that + and — deviations of any given magnitude are equally frequent; that small deviations are more frequent than large ones; that very large ones occur very seldom.

In such a series we should readily admit that sensibly all sources of *error* must have occurred in all possible ways. If so, we should suppose from the laws of chance, considered purely from a mathematical standpoint, that probably + and — errors of any given magnitude would be equally frequent, that small errors would be more frequent than large ones, and that very large errors would occur very seldom. But these statements are identical with those just found actually to hold for the deviations from the mean in the same series. Thus, *for such a series, the deviations may be assumed as sensibly coincident with the errors, and the mean with the true result,* which justifies the statement made at the outset (p. 44).

Best representative value. But the indefinitely large series is, of course, unattainable in practice, when the number of observations must generally be small. For smaller series the distribution of the *individual results about the mean* may be (usually is) approximately the same as for large series,—more closely as the number is larger, but as already stated in other words, we have no assurance that the deviations are accidental *errors*, as the mean may be, and very likely is, affected by some considerable resultant or constant error. The process of averaging *tends* to the elimination of the variable parts of the errors; and it may therefore be shown by the theory of probabilities, or experimentally, that even for small series the arithmetical mean is the best representative value, *provided that determinate errors have, as far as discoverable, been removed.* That is, the mean is the most probable value,—the one which in the long run will give the closest approach to the true result. Since the mean and true result will generally not coincide, there will be residual errors. These will themselves, in the long run, be distributed according to the general law of accidental errors, which is another indication that the mean is the best value to use. For that would naturally be the best value which, in the long run, would so distribute the residuals that their algebraic sum would be zero.

It thus appears that in order to get at a measure or

estimate of the accuracy of the result of a completed investigation, we must study, first, all discoverable sources of error, in order to ascertain how far those which are determinate have been corrected or eliminated. Second, we must compute a measure of the disturbance due to the *variable portion* of the remaining indeterminate sources of error, so far, at least, as the measure of precision (below) will give this. But it must always be remembered that beyond all this there *may*, and in general *must*, remain undetected "constant" errors. The discussion of the determinate errors is by far the most important of the two points above referred to. The discovery of an undetected source of error in a result, furnishes, of course, a means of estimating its minimum error, or possibly of correcting it. If several measurements of the same quantity by different processes and observers exist, then the study of each, and the comparison and combination of all, will furnish the best available means of estimating the accuracy of the knowledge regarding that quantity.

The ideal procedure in a quantitative investigation would be this: Make a preliminary survey of the ground to be covered. Then make a detailed survey, and map out the general method and theory of the work. This includes studies of the apparatus to be used; of the procedure in observing; of the method of computing or "reducing" the results (the importance of having this thoroughly worked out in advance is very great); of the determination of the conditions under which the observations are to be made; of the distribution of accuracy necessary in the component measurements; of the nature of the instrumental and other corrections; of the best means of obtaining check results, etc. Next would come the preliminary observations of evaluating, *i. e.*, determining the value of, the corrections, etc. Then come the measurements proper of the investigation. Finally, there is the reduction, discussion, and presentation of these results. These last include not merely a computation and tabulation of the numerical results, but a complete discussion of their significance, a critical review of the work, and a thorough presentation of the whole, with data, when practicable, sufficient for a re-discussion of the work by others.

Three points may be mentioned in which quantitative investigations often fail to satisfy reasonable demands. First, the theory of the method is insufficiently studied in advance of the measurements, so that the adjustment of accuracy in the various component parts of the work is faulty, and the determinate errors are incompletely eliminated. Second, the results are presented in a very imperfectly digested form, so that but a very small part of their proper outcome and significance is obtained. Third, the data and results are so meagerly given that it is impossible to form any independent judgment of the real merit of the work.

It is not superfluous to remark that the sole object of scientific investigation is the ascertainment of truth; and scientific work to be deserving of such classification must be conducted throughout in this spirit. The scientific observer must not only be above suspicion, but must be continually on his guard against bias and prejudice. Also, as the object of most investigation is to add to the known truth, it goes without saying that the worker should never fail to equip himself beforehand with a knowledge of all that has been previously done in the line of his proposed work. Independent corroboration of work is of very great value; but it is likely to be of greater value when done in view of, than when in ignorance of, previously existing work.

The topics and formulæ necessary for the discussion of the relative distribution of precision in the component measurements of a complex quantity, of the best conditinos for making certain measurements, and other analogous matter, will be now taken up, and illustrative examples will be given.

Measure of precision. Bearing in mind the denotation already fixed upon for the terms accuracy and precision, it will be understood that the precision measure can never be anything more than an index or measure of the accordance of the single observations in a series, or of the separate results (means or single observations) composing a group. For most physical uses the simplest and most direct measure of precision should be preferred, and this is the *average deviation.* In addition to simplicity of computation, this has the merit that its name states exactly what it is, and all that it is, and no more. It is free from the liability to mislead which embarrasses the use of such terms as "probable error," "mean error," etc., these being stumbling-blocks to beginners, and a frequent cause of misapprehension even to those who know the true meaning of the terms.

The *average deviation* of the single observations from the mean will be indicated by *ad.* This will denote the average *magnitude* of the deviations, and it may be computed by the formula

$$ad = \frac{\Sigma d}{n} \qquad \text{I.}$$

where, therefore, Σd is the arithmetical sum of the deviations without regard to algebraic sign. Since a mean result is more precise than a single observation in the proportion of the square root of the number of the observations from which it is deduced, we should have, as a corresponding measure of the precision of the mean,

$$A\,D = \frac{a\,d}{\sqrt{n}} \text{ or } = \frac{\Sigma\, d}{n\sqrt{n}} \qquad \text{II.}$$

which would be called the average deviation of the mean.

Instead of ad and $A\,D$ are often employed the "probable errors," which may be computed as

$p\,e = 0.674\sqrt{\frac{\Sigma d}{n-1}}$, or approximately 0.85 $a\,d$, or 0.9 ad,

and $PE = \frac{p\,e}{\sqrt{n}}$. The "error of mean square" $=$

$\sqrt{\frac{\Sigma d^2}{n-1}}$ has been employed to a considerable extent in Germany.

The formula for the average deviation for indefinitely large series of observations following *any* law of distribuion may be deduced thus:—

$\Delta =$ a deviation.

Let $\varphi(\Delta) =$ the law of deviation. The general law of deviations already referred to (p. 45) is not the only one; another is given further on in these notes. $\varphi(\Delta)$ is such a function that

$\varphi(\Delta)\cdot d\Delta =$ the probability that any single observation will have a deviation lying between Δ and $\Delta + d\Delta$; or $\varphi(\Delta).d\Delta =$ the "frequency" of occurrence of observations with deviations within that limit.

$n =$ total number of observations in the series.

$\therefore n\cdot\varphi(\Delta)\cdot d\Delta =$ *number* of observations with deviations between Δ and $\Delta + d\Delta$.

$n\Delta.\varphi(\Delta)\cdot d\Delta =$ sum of all the deviations between Δ and $\Delta + d\Delta$.

$\int_0^\infty n\Delta\cdot\varphi(\Delta)\cdot d\Delta =$ sum of all the deviations between $\Delta = \infty$ and $\Delta = 0$, *i. e.*, of all the positive deviations.

$$2\int_0^\infty n\Delta.\varphi(\Delta)\cdot d\Delta = \text{sum of magnitudes of the } n \text{ deviations.}$$

$$\frac{-}{n}\int_0^\infty n\Delta\cdot\varphi(\Delta)\cdot d\Delta = ad = \text{average of all the deviations between } +\infty \text{ and } -\infty, \ i.\ e., \text{ average magnitude.}$$

$$\therefore ad = 2\int_0^\infty \Delta\cdot\varphi(\Delta)\cdot d\Delta. \qquad \text{III.}$$

If the deviations range only between the limits $+a$ to $-a$

$$ad = 2\int_0^a \Delta\cdot\ \varphi(\Delta)\cdot d\Delta. \qquad \text{IV.}$$

In any individual case it is therefore necessary to know a and $\varphi(\Delta)$ in order to have a determinate expression for ad.

Special law of deviations. 1st. There frequently occurs in practice the case where all values of Δ between $\Delta = +a$ and $\Delta = -a$ are equally likely to be obtained; *i. e.*, are equally frequent. Then $\varphi(\Delta) =$ a constant. Bearing in mind that the sum of all possibilities must be always unity, and also the above definition of $\varphi(\Delta)$, we have $\int_{-a}^{+a}\varphi(\Delta)\cdot d\Delta = 1$. Remembering that $\varphi(\Delta)$ is constant, and integrating gives $\varphi(\Delta)\int_{-a}^{+a} d\Delta = 1$

$$= 2\,a\,\varphi(\Delta);$$

$$\therefore \varphi(\Delta) = \frac{1}{2a}, \text{ and } a\,d = 2\int_0^a \Delta\cdot\varphi(\Delta).d\,\Delta = \frac{a}{2} \qquad \text{V.}$$

2d. Two independent and simultaneous sources of deviation, each following the law of 1st case.

$$a\,d = \tfrac{2}{3}\,a. \qquad \text{VI.}$$

Other cases may arise. [Both the foregoing and this demonstration are from Wright's "Adjustment of Errors of Observation."]

Principle of least squares. From the general law of distribution of deviations, or accidental errors, two deductions of importance may be made, viz.:—

1. That in combining a large number of equally reliable observations, whether direct or indirect, and whether of one or several independent variables, the most probable, or "best" result will be that which makes the sum of the squares of the deviations from that result a minimum. This is called the principle of least squares, and finds wide application. The use of the arithmetical mean may be shown to be in accordance with this principle.

2. That of means deduced respectively from n_1, n_2, etc., measurements, all equally reliable, the relative precision is in proportion to the square roots of the number of measurements; that is, of $\sqrt{n_1} : \sqrt{n_2}$ etc. Thus the mean of n equally reliable results is more precise than a single observation in the proportion of $\sqrt{n} : 1$; and hence $AD = \frac{a\,d}{\sqrt{n}}$ may be used as the precision measure of the mean, as stated at p. 46.

If the measurements are not all equally reliable, they may be made so by the application of their respective weights. It is shown from the law of deviations, that the weights of observations are inversely proportional to their AD^2, PE^2, etc. Let p denote the weight, then

$$p_1 : p_2 : p_3 = \frac{1}{A\,D_1^2} : \frac{1}{A\,D_2^2} : \frac{1}{A\,D_3^2}$$

$$= \frac{1}{PE_1^2} : \frac{1}{PE_2^2} : \frac{1}{PE_3^2} = \text{etc.} \qquad \text{VII.}$$

In all the formulæ to be given, it will be assumed that the means and combinations are always made with due regard to weights.

Combination of changes in component measurements. Suppose an indirectly determined quantity, M, to be related to the several *independent*, observed quantities, M_1, M_2, . . . M_n, from which it is computed by the general expression

$$M = f(M_1, M_2, \ldots M_n, \qquad \text{VIII.}$$

Separate effects. 1st. What effect would a change δ or δ_2, etc., in any one of the variables M_1, M_2, etc., taken separately, have on M? It is obvious that this may be found from the differential of M with respect to M_1 or M_2, etc. Thus, for example, denoting for brevity, $f(M_1\ M_2, \ldots M_n)$ by $f(\ )$,

$$\frac{d\,M}{d\,M_1} = \frac{d}{d\,M_1}\Big(f(M_1, M_2, \ldots M_n)\Big); \text{ or}$$

$$\frac{d\,M}{d\,M_1} = \frac{d\,f(\,)}{d\,M_1}; \text{ etc.} \qquad \text{IX.}$$

For finite changes, δ or Δ, we have the approximation $\frac{d\ M}{d\,M_1} = \frac{\Delta' M}{\delta_1}$, etc., whence approximately,

$$\frac{\Delta' M}{\delta_1} = \frac{d\,f(\,)}{d\,M_1},\quad \Delta' M = \frac{d\,f(\,)}{d\,M_1}.\,\delta_1,\quad \Delta'' M = \frac{d\,f(\,)}{d\,M_2}.\,\delta_2, \text{ etc.} \qquad \text{X.}$$

2d. What changes, δ_1, δ_2, etc., in the components M_1, M_2, etc., would, if taken separately, each produce an assigned change $\Delta' M$, $\Delta'' M$, etc., in M? Obviously, this is merely the converse of the 1st case, whence

$$\frac{\Delta' M}{\delta_1} = \frac{d\,f(\,)}{d\,M_1}, \text{ etc.}$$

$$\therefore \delta_1 = \Delta' M \Big/ \frac{d\,f(\,)}{d\,M_1},\ \delta_2 = \Delta''\ M \Big/ \frac{d\,f(\,)}{d\,M_2}, \text{ etc.} \qquad \text{XI.}$$

Combined or collective effects. The principle of least squares shows that for the general case where $M = f(M_1, M_2, \ldots M_n)$, M_1, M_2, etc., being *independent* variables, the combined effect of the separate changes $\Delta' M$, $\Delta'' M$, etc., will be given *best*; *i. e.*, given with greatest probability in the long run, by the expression

$$(\Delta M)^2 = (\Delta' M)^2 + (\Delta'' M)^2 + \ldots + (\Delta'' M_n)^2 \qquad \text{XII.}$$

which accords with the statement made previously in the paragraphs above. Hence, by substituting the above equivalents of $\Delta' M$, $\Delta'' M$, etc., and, for simplicity, writing Δ for ΔM, we have the following formulæ: Those for the special values of $f(M_1, M_2, \ldots M_n)$ are deduced directly from the general case by inserting the values of $f(\ )$, and performing the differentiation. $b =$ a known constant.

$$M = f(M_1, M_2, \ldots M_n)$$

$$\Delta^2 = \left(\frac{d\,f(\,)}{d\,M_1}.\,\delta_1\right)^2 + \left(\frac{d\,f(\,)}{d\,M_2}.\,\delta_2\right)^2 + \ldots + \left(\frac{d\,f(\,)}{d\,M_n}.\delta_n\right)^2 \qquad \text{XIII.}$$

$$M = M_1 \pm M_2 \pm \ldots \pm M_n$$

$$\Delta^2 = \delta_1^2 + \delta_2^2 + \ldots + \delta_n^2 \qquad \text{XIV.}$$

$$M = b_1 M_1 \pm b_2 M_2 \pm \ldots \pm b_n M^n$$

$$\Delta^2 = (b\,\delta_1)^2 + (b_2\delta_2)^2 + \ldots + (b_n\,\delta_n)^2 \qquad \text{XV.}$$

$$M = b\cdot M_1 \ldots M_1 \cdot M_n$$

$$\left(\frac{\Delta}{M}\right)^2 = \left(\frac{\delta_1}{M_1}\right)^2 + \left(\frac{\delta_2}{M_2}\right)^2 + \ldots + \left(\frac{\delta_n}{M_n}\right)^2 \qquad \text{XVI.}$$

$$M = \frac{b_1\,.\,M_1 \ldots}{b_2\,.\,M_2 \ldots}$$

$$\left(\frac{\Delta}{M}\right)^2 = \text{same as preceding.} \qquad \text{XVII.}$$

$$M = b \,.\, M_1^{\pm n} \quad \Delta^2 = \left(\frac{d f M_1}{d M_1} . \delta_1\right)^2 = \left(\pm n b M_1^{\pm n - 1} \delta_1\right)^2$$

$$\therefore \left(\frac{\Delta}{M}\right)^2 = \left(\frac{\pm n \delta_1}{M_1}\right)^2 \quad \therefore \frac{\Delta}{M} = \pm \frac{n \delta_1}{M_1} \qquad \text{XVIII.}$$

$$M = \varphi(M_1) \cdot \rho(M_2) \ldots \sigma(M_n)$$

$$\left(\frac{\Delta}{M}\right)^2 = \left(\frac{d \varphi(M_1)}{d M_1} \cdot \frac{\delta_1}{\varphi(M_1)}\right)^2 + \left(\frac{d \rho(M_2)}{d M_2} \cdot \frac{\delta_2}{\rho(M_2)}\right)^2 + \cdots + \left(\frac{d \sigma(M_n)}{d M_n} \cdot \frac{\delta_n}{\sigma(M_n)}\right)^2 \qquad \text{XIX.}$$

$$\left(\frac{\Delta}{M}\right)^2 = \left(\frac{\delta \varphi(M_1)}{\varphi(M_1)}\right)^2 + \left(\frac{\delta \rho(M_2)}{\rho(M_2)}\right)^2 + \cdots + \left(\frac{\delta \rho(M_n)}{\rho(M_n)}\right)^2 \qquad \text{XX.}$$

Of the special cases, the two most common may readily be put into words. When the f is the sum or difference, the square of the resultant change *in units* = the sum of the squares of the component changes *in units*. When f is a product, or quotient, the square of the resultant *fractional* change = the sum of the squares of the component *fractional* changes. The last special case calls for the following further notice.

Separation into factors. We have often to deal with an expression which is a somewhat complicated function of several independent variables, so that its differentiation is cumbrous, but which may readily be separated into factors, each of which is a function of *but one* independent variable. Factoring thus would give $M = \varphi(M_1) . \rho(M_2) \,.\,.\, \sigma(M_n)$ as in XIX. Then substituting in XIII, and carrying the differentiation as far as we can, *i. e.*, to the indicated differential $\frac{d\varphi(M_1)}{d M_1}$, etc., we deduce the form of XIX. But if for differentials we substitute finite changes, we may write for $\frac{d\varphi(M_1)}{d M_1}$, $\frac{\delta \varphi(M_1)}{\delta M_1}$; etc. Then

$$\left(\frac{\Delta}{M}\right)^2 = \left(\frac{\delta \varphi(M_1)}{\delta M_1} \cdot \frac{\delta_1}{\varphi(M_1)}\right)^2 + \left(\frac{\delta \rho(M_2)}{\delta M_2} \cdot \frac{\delta_2}{\rho(M_2)}\right)^2 + \cdots + \left(\frac{\delta \sigma(M_n)}{\delta M_n} \cdot \frac{\delta_n}{\sigma(M_n)}\right)^2$$

which becomes identical with XX when we cancel δ and δM_1, which are merely two expressions for the same quantity, provided that we remember that $\delta \varphi(M_1)$ etc., are the changes due to δ_1, etc., in the variables M, etc. This process is often a convenience, and illustrations of its use will be given later. In words, expression XX becomes, the square of the resultant fractional change = the sum of the squares of the fractional changes *in the factors*.

Applications. For present purposes these formulæ are to be used in computing the effects upon the final result due to deviations or errors in the component measurements. The values to be used for δ will thus be precision measures or errors, as the case may be. The discussions will be intended to apply especially to cases where the number n of the variables is small, as is usual in physical work. In order to secure for the formulæ the most favorable conditions, the value of n being in general small, no determinate error should be allowed to enter into the precision measures. If the effect of such is under consideration, it must be separately studied by independent differentiation. Such cases often occur in considering the effect of omitting known corrections, or of dropping significant figures from known numerical constants, etc.

It has been shown already that when all determinate sources of error have been as far as possible eliminated, there remain only precision measures to be considered. Hence in the equations for collective effects, we have properly to deal only with precision measures as δ's, and thus the resulting Δ is a precision measure of the same kind as the δ's. In any single equation, of course, all the δ's must be of the same kind; *e. g.*, all must be *ad*'s and *AD*'s, or all *pe*'s and *PE*'s, etc. A $\delta_1 = ad$ may obviously be combined with a $\delta_2 = AD$, if M_1 is a single measurement and M_2 a mean, but an *ad* cannot be combined with a *pe*. The resulting Δ will necessarily be an *ad* if any one or more of the δ's is an *ad*; but if all δ's are AD's, then the Δ may of course be regarded as a AD. This classification of the Δ is, however, unimportant. The point is, that Δ is the *precision* measure of the result M. If any component, *e. g.* M_1, were obtained as a direct uncorrected measurement, then its δ would be simply the average deviation of the measurement. But if this component M_2 is in itself a complex or indirect quantity, as is usual, its δ must include the measures of all sources of deviation, viz., from observations, corrections, component measurements, etc.

The formulæ are applicable to two somewhat distinct cases.

1st. Given values of $\delta_1, \delta_2, \ldots, \delta_n$ to compute their effect, either separately or together, on M.

2d. Prescribed a definite limit of precision or accuracy in the final result; to compute beforehand what grade of *precision* or *accuracy* (to be expressed by δ_1, δ_2, etc.) is necessary in each component in order that the final result shall not be affected beyond the assigned limit.

In the second of these applications it is, of course, essential to know beforehand roughly approximate values of the various quantities, M_1, M_2, etc., but very roughly measured, and even estimated or computed values, are usually sufficient. Thus these applications can generally be made in advance of the construction of apparatus for an investigation, and may serve to show whether a proposed investigation, or instrument, or process, probably can or cannot be made to yield a desired result, or to show what the proportion of parts and the arrangement of apparatus should be. They enable us also to deduce rules for the use of places of significant figures.

Distribution of precision amongst components. In making the second application, it is necessary to determine beforehand upon some relative distribution of precision amongst the components. The simplest would be that which would assign to the δ's such values that *each* should produce an *equal effect* on the final result. But this would not be invariably the best distribution, since it might conceivably demand an amount of labor in making one or more of the measurements which would be widely disproportionate to that involved in making the others. It cannot, however, be much departed from, and should usually be the basis of computation. Yet it is always of advantage to make any δ smaller than this requirement would indicate, if this can be done with little more than an equal share of labor; provided, however, that it be understood that there is but slight advantage in reducing any δ much below one-tenth of its value for equal effects. The general solution for "equal effects" is given below.

Formulæ for equal effects. The formula for the "combination of errors" for the general case $M = f(M_1, M_2 \ldots M_n)$ has been given at p. 47, as M_1, etc., being independent variables,

$$\Delta^2 = \left(\frac{d f()}{d M_1} . \delta_1\right)^2 + \left(\frac{d f()}{d M_2} . \delta_2\right)^2 + \ldots + \left(\frac{d f()}{d M_n} . \delta_n\right)^2 \quad \text{XIII}$$

Now, in order that each δ should have an equal effect on Δ, *i. e.*, that each source of deviation should have an equal effect with each of the others on the final result, the terms of the second member must be all equal. Thence,

$$\frac{d f()}{d M_1} . \delta_1 = \frac{d f()}{d M_2} . \delta_2 = \ldots = \frac{d f()}{d M_n} . \delta_n = \frac{\Delta}{\sqrt{n}} \quad \text{XXI.}$$

Hence,

$$\delta_1 = \frac{\Delta}{\sqrt{n}} \Big/ \frac{d f()}{d M_1}\,; \quad \delta_2 = \frac{\Delta}{\sqrt{n}} \Big/ \frac{d f()}{d M_2}\,; \ldots;$$

$$\delta_n = \frac{\varDelta}{\sqrt{n}} \Big/ \frac{d f()}{d M_n} \qquad \text{XXII.}$$

Ordinarily, the assigned limit for error in M is given as a fraction of M; *i. e.*, as $\frac{\varDelta}{M}$, or as a percentage, which would be $100 \frac{\varDelta}{M}$. Of course the corresponding numerical value of $\varDelta$ may be at once computed by multiplying by M, for $\varDelta = \frac{\varDelta}{M} . M$.

Applying the condition of equal effects to some special cases, we have the following :—

For $M = M_1 \pm M_2 \pm \ldots \pm M_n$,

$$\varDelta^2 = \delta_1^2 + \delta_2^2 + \ldots + \delta_n^2 \qquad \text{XIV.}$$

Hence for equal effects of δ_1, δ_2, etc.,

$$\delta_1^2 = \delta_2^2 = \ldots = \delta_n^2 = \frac{\varDelta^2}{n}$$

$$\therefore \delta_1 = \delta_2 = \ldots = \delta_n = \frac{\varDelta}{\sqrt{n}} \qquad \text{XXIII.}$$

$$\text{For } M = b \cdot M_1 \cdot M_2 \ldots M_n, \left(\frac{\varDelta}{M}\right)^2$$

$$= \left(\frac{\delta_1}{M_1}\right)^2 + \ldots + \left(\frac{\delta_n}{M_n}\right)^2 \qquad \text{XVI.}$$

Hence for equal effects,

$$\frac{\delta_1}{M_1} = \frac{\delta_2}{M_2} = \ldots = \frac{\delta_n}{M_n} = \frac{1}{\sqrt{n}} . \frac{\varDelta}{M} \qquad \text{XXIV.}$$

For $M = \varphi(M) \cdot \rho(M_2) \ldots \sigma(M_n)$,

$$\left(\frac{\varDelta}{M}\right)^2 = \left(\frac{\delta \varphi(M_1)}{\varphi(M_1)}\right)^2 + \left(\frac{\delta \rho(M_2)}{\rho(M_2)}\right)^2 + \ldots + \left(\frac{\sigma(\delta M_n)}{\sigma(M_n)}\right)^2 \qquad \text{XX.}$$

Hence for equal effects,

$$\frac{\delta \varphi(M_1)}{\varphi(M_1)} = \frac{\delta \rho(M_2)}{\rho(M_2)} = \ldots = \frac{\delta \sigma(M_n)}{\sigma(M_n)} = \frac{1}{\sqrt{n}} . \frac{\varDelta}{M} \qquad \text{XXV.}$$

i. e., in this "separation into factors" the *fractional change* in every *factor* is the same, and is equal to $1 / \sqrt{n}$ of the resultant or assigned fractional change in M. In general, however, we wish to find the changes not in the factors, but in the observed variables M_1, $M_2 \ldots M_n$. But having deduced the change in any factor, we may, of course, deduce the corresponding change in the variable contained in that factor by direct differentiation. For the change $\delta\varphi(M_1)$, produced by the change $\delta M_1 (= \delta_1)$, is given by the differential of $\varphi(M_1)$ with respect to M_1. That is,

$$\frac{\delta \varphi(M_1)}{\delta_1} = \frac{d \varphi(M_1)}{d M_1}$$

whence,

$$\delta_1 = \delta \varphi(M_1) \Big/ \frac{d \varphi(M_1)}{d M_1} \qquad \text{XXVI.}$$

similarly,

$$\delta_2 = \delta \rho(M_2) \Big/ \frac{d \rho(M_2)}{d M_2} \text{ ; etc.}$$

The numerical values of $\delta \varphi(M_1)$, etc., for substitution in these are obtained, of course, from the fractional changes in the factors by multiplying these fractions by the numerical values of $\varphi(M_1)$, etc. That is,

$$\delta \varphi(M_1) = \frac{1}{\sqrt{n}} . \frac{\varDelta}{M} . \varphi(M_1),$$

$$\delta \rho(M_2) = \frac{1}{\sqrt{n}} . \frac{\varDelta}{M} . \rho(M_2), \text{ etc.} \qquad \text{XXVII.}$$

Or we may combine these two steps algebraically, and get

$$\delta_1 = \frac{1}{\sqrt{n}} . \frac{\varDelta}{M} . \varphi(M_1) \Big/ \frac{d \varphi(M_1)}{d M_1} \ldots \qquad \text{XXVIII.}$$

$$\delta_2 = \frac{1}{\sqrt{n}} . \frac{\varDelta}{M} . \rho(M_2) \Big/ \frac{d \rho(M_2)}{d M_2} \text{ etc.}$$

And these expressions may be seen, by inspection to be identical with those which would have been obtained had XIX been subjected directly to the condition of equal effects.

In this method of using factors, it must be borne in mind that the results for δ_1, δ_2, etc., are the same as would be obtained by a direct application of the general process only when the factors are wholly independent of each other. Yet in some cases it is convenient to separate into factors which are not wholly independent. Such a process would, however, seldom be used unless the factors were but slightly dependent; for instance, where the variable of one factor entered into another factor merely in a small correction term, or in some other way, in which the resulting values of δ were not sensibly affected by the irregular separation.

Simplification of functions. Since the aim usually is to find, only roughly, approximate values of the δ's corresponding to an assigned $\varDelta$, much labor may be often saved by simplifying, as far as possible, the function $f(M_1, M_2, \ldots, M_n)$ before differentiation. The nature of the simplification would depend on the case in hand, and might consist in omitting small correction terms, the use of approximate formulæ, etc. Also, in the same investigation, it might be possible to use approximate or simplified function in studying some variables, and the complete function in studying others, and different simplifications for various parts of the work.

STATISTICS OF UNITED STATES PATENTS RELATING TO ELECTRICITY, ISSUED IN 1887.

COMPILED BY THOS. D. LOCKWOOD.

In the year 1887, there were issued from the United States Patent Office patents to the number of 20,429. In 1886 there were issued 21,797. In 1885 there were issued 23,330. The year 1887 thus shows a decrease of 1,368 as compared with 1886, and of 2,901 with respect to 1885. Of the patents of 1887, 1248 were issued upon electrical inventions, or upon inventions closely allied to electricity, such as mechanical telephones, a decrease of 89 from last year. The electrical patents of 1887 constitute 6.10% of the whole; as against a percentage of 6.13 last year.

Classified, the electrical inventions patented are as follows:

Telegraphy: Sub-divided into classes:

1. Autographic, Automatic and chemical telegraphs..	6
2. Keys, relays, sounders, repeaters, etc	12
3. Multiple telegraphs	14
4. Printing telegraphs	26
5. Novel systems, etc	18
Total	76
Total in 1886	78

Conductors, insulators and supports are divided as follows:

1. Cables, compound conductors and their manufacture	18
2. Couplings and connectors	30
3. Insulated wires and flexible cords	9

4.	Insulators for pole lines	5
5.	Insulating materials and compounds	10
6.	Line wire, construction, etc	3
7.	Supports, poles, fixtures, cable hangers	16
8.	Underground systems, etc	88
	Total	129
	Total in 1886	125

Patents relating in a greater or less degree to telephony are contained in the following sub-classes :

1.	Battery telephones, or transmitters	31
2.	Magneto and other receiving telephones	19
3.	Telephonic relays and repeaters	0
4.	Telephone central station apparatus	24
5.	Telephone signals	13
6.	Telephone exchange systems and circuit arrangements	15
7.	Induction remedies, etc	5
8.	Individual calls	2
9.	Guards against abnormal currents, and lightning arresters and rods	25
10.	Switch-boards	10
11.	Miscellaneous telephonic utilizations	25
12.	Mechanical telephones	31
	Total	200
	Total in 1886	232

Next come patents relating to the distribution of electricity and its employment in the transmission of power. These are :

1.	Distribution of electricity	38
2.	Railways and motors therefor	20
3.	Transmission of power, telpherage, etc	54
	Total	112
	Total in 1886	132

Patents concerning sources of electricity and its development are as follows :

1.	Batteries—primary	70
2.	" —secondary	20
3.	Dynamos, and magneto machines	40
4.	Dynamo regulators	23
	Total	153
	Total in 1886	173

Electrical illumination has the following showing :

1.	Arc lamps	35
2.	Incandescent lamps	47
3.	Lamp, and electric light fixtures	22
4.	Lighting apparatus, cut-outs and other appliances	21
	Total	125
	Total in 1886	157

Finally, we have a list of well-known applications of electricity which are bunched, because they cannot conveniently be classified otherwise.

1.	Annunciators, indicators, and alarms	62
2.	Burglar alarm and watch clock systems	11
3.	Clocks—synchronizing and time systems	30
4.	Circuit breakers, closers, changers and controllers	24
5.	Electro-magnets, armatures and induction coils	17
6.	Electro-metallurgy	14
7.	Fire and heat alarms, and district telegraphs	59
8.	Measurement, galvanometers, etc	28
9.	Gas lighting	14
10.	Railroad signals and train telegraphs	34
	Total	293
	Total in 1886	314
	Unclassified applications	160
	Unclassified applications, 1886	126

As before stated, the grand total of electrical patents is 1,248.

Alphabetically considered, the inventors' names are classified in the following manner :

Patentees under the initial A = 22 ; B = 125 ; C = 82 ; D = 50 ; E = 59 ; F = 51 ; G = 45 ; H = 100 ; I = 3 ; J = 27 ; K = 32 ; L = 51 ; M = 89 ; N = 14 ; O = 11 ; P = 63 ; Q = 1 ; R = 39 ; S = 151 ; T = 76 ; U = 2 ; V = 19 ; W = 131 ; X = 0 ; Y = 2 ; Z = 3. Total 1,248.

It will be seen that S, has resumed the place of honor, W, B and H coming next. Q does itself proud with one ; while X, is as usual unrepresented.

ELECTRIC ENERGY FROM CARBON WITHOUT HEAT.[1]

BY WILLARD E. CASE.

THE following experiments, undertaken by the author, may be of interest as indicating the way in which the cheap generation of electrical energy may possibly be brought about.

In the first experiment an element was formed through which heat energy was converted into electrical energy, in which the correlation of forces is beautifully illustrated.

It is a sort of voltaic battery, in which plates of tin and platinum forming the electrodes are immersed in a solution of chromic chloride, which has no action on the plates at ordinary temperature, so no current is generated. The cell is hermetically sealed, and when heated the liquid becomes active, and part of one of its elements, chlorine, leaves the chromic chloride, goes over and temporarily combines with the tin, forming a proto-chloride of tin. The chemical action generates an electric current, but soon the tin is all converted into chloride, and the current ceases. When the cell is cooled, this temporary combination of the chlorine and tin is broken up, and the chlorine returns to the chromium proto-chloride. The tin being set at liberty, falls as a metallic precipitate to the bottom of the cell in the form of crystals, ready to renew the combination when the cell is again heated. None of the materials of the element are destroyed; they last an indefinite time. The chlorine changes from chromic chloride to tin and back, as often as the cell is heated and cooled.[2]

It is well known that the voltaic battery converts the potential energy of a metal directly into electricity, without heat. This cell, similar to the voltaic battery, converts heat into electricity. The voltaic battery acts at ordinary temperatures, giving up all the energy stored in the metal, and there is the end of it ; while this cell acts only when heat is applied to it, converting part of this heat into electricity. After the tin has all been converted into chloride the cell becomes inert, no matter how much more heat be applied. The cell must then be cooled to get this tin back into the metallic state, so here it is necessary to have a difference of temperatures, the tin and liquid being simply a medium by which heat is transformed into electric energy.

It will probably be found that the solution of the tin absorbs heat, and so tends to cool the liquid, and the precipitation develops heat, and so tends to warm the liquid, and that the part where the solution occurs must be kept warmer than that where the tin precipitates. An investigation would probably show that when electric currents are generated the heat absorbed by the solution of the tin is in excess of that generated by the precipitation, by the equivalent of the electrical energy developed, and that the possible excess is governed by the second law of thermodynamics. If the cell works between 80° and 180° F., the E. M. F. at the higher temperature is about 0.26 volt, the efficiency is less than 16 per cent., as the possible efficiency $= \frac{T-t}{T}$ reckoned from absolute zero, or $\frac{638^\circ - 538^\circ}{638^\circ} = .157$.

In fact, this cell is a heat engine, analogous to the thermopile, which is said to convert only 2 per cent. of the energy of the coal into electric energy. In practice, probably nothing like 16 per cent. could be utilized.

It is an inexorable law of nature, that under the conditions in which we live a great waste must accompany the transformation of heat into any other form of energy. In the condensing steam engine it requires to condense the steam, four or five pounds of water to every pound of

1. Read before the American Institute of Electrical Engineers, January 10, 1888.

2. This cell has been described in *Proc. Roy. Soc.*, No. 244, 1886.

steam. Three-fourths the heat used goes to warm that water, and is wasted. In hot air engines or gas engines a cold water jacket must be used, and to it goes the larger share of the heat employed. In the thermopile one set of junctions must be kept cool by circulation of air or water. In Edison's pyro-magnetic generator the iron tubes must be cooled by a blast of cold air.

By the second law of thermo-dynamics the minimum amount of heat that goes to this cooling agent is the fraction $\frac{t}{T}$ of the total amount employed, where t is the temperature of the cooler reckoned from the absolute zero and T the higher temperature of the working substance; t can not be less than about 500°, so the numerator of the fraction is always large, and the heat wasted is the larger portion. Understand that this is a law of nature; it is inevitable under the conditions in which we live. No cunningly devised furnace, or feed-water heater, or cut-off, or triple expansion apparatus, or pyro-generator can save this heat. The most that any of these devices can do is to save what would otherwise be wasted over and above the proportion $\frac{t}{T}$. But are we to go on wasting all this energy of fuel? Cannot some means be employed to utilize it? We know that the voltaic battery is not a case of the transformation of heat into electrical energy; it produces electrical energy directly. The second law of thermo-dynamics does not apply, as no heat appears. If we could convert the chemical energy of coal and oxygen into electric energy, directly and cheaply, we would do away with all our steam motors at once. There is no known reason why a cheap substance may not be found which will act on coal and develop electric currents in place of heat. This electric energy would be the equivalent of the heat energy that would be developed by the combustion of the same coal in the ordinary way, and could be transformed into mechanical power, heat, light, etc., with small loss.

So far, little progress has been made in this direction. Some time ago, Jablochkoff produced a battery in which plates of carbon and iron were immersed in fused nitre. The carbon being oxidized, furnished strong currents. The objection to this element is the generation of heat through local action. To it the second law does not apply. Another experiment of more interest than the first is an illustration of an element which is not affected by the second law, as heat is not essential to its operation. The energy due to the complete oxidation of carbon is converted into electric energy directly.

In a glass cell containing sulphuric acid, C. P. Sp. Gr. 1.81, temp. 75 Fah., two electrodes were immersed, one of platinum, the other of lump graphite; only a slight E. M. F. was indicated, 0.007 volt, due to the combination, the graphite acting as a positive element; on the addition of a small quantity of chlorate potassium to the acid, the E. M. F. immediately rose to 00.8 volt, the graphite being disintegrated after a time. This cell polarized rapidly, which was partially prevented by mechanical means. The reaction of chlorate potassium with sulphuric acid may be represented by the following equation: $3\ KClO_3$ (chlorate of potassium) $+\ 2\ H_2SO_4$ (sulphuric acid) $=\ 2\ ClO_2$ (peroxide of chlorine) $+\ KClO_4$ (perchlorate potassium) $+\ 2\ KHSO_4$ (acid sulphate of potassium) $+\ H_2O$ (water).

A method of exclusion was adopted to ascertain the oxidant of this electrolyte; chlorine peroxide (ClO_2) appeared to be the only active agent. It is decomposed by the carbon, chlorine being evolved with some oxygen. It was assumed that in this cell graphitic acid ($C_{11}H_4O_5$) was formed[1] as the result of the chemical actions. There is probably much waste of energy through local action, as the chemical reactions go on when the circuit is open, but to a less extent. In another experiment an electrolyte was formed of sulphuric acid and chlorine peroxide, the gas being formed in a retort by the action of sulphuric acid on chlorate potassium, and conducted over into the acid in which it was dissolved. This cell, with a positive element of graphite, opposed to platinum, gave an E. M. F. of 0.7 volt.[2]

A similar combination was used with a solution of chlorine peroxide in water as the electrolyte. The E. M. F. assigned to these cells is only approximate, as it was found dependent on the quantity of chlorine peroxide in solution, which was constantly changing. The resistance also varied with the different degrees of concentration of the exciting fluid.

Different forms of amorphous carbon were substituted in place of graphite in the first form of cell. Gas carbon gave an E. M. F. 0.007 volt when opposed to platinum in sulphuric acid; on the addition of chlorate potassium the E. M. F. rose to 0.5 volt.

Carbon, produced by the action of sulphuric acid on cane sugar, in this experiment gave an E. M. F. of 0.3 volt.

The carbon of animal charcoal, wood charcoal, coke and anthracite, gave an E. M. F. variable with each form, ranging from 0.3 volt to 1.25 volt. The measurements of E. M. F. of the various combinations were made with the electrode immersed in separate parts of the same solution, that the concentration of the liquid and quantity of gas in solution might be as nearly equal in each cell as possible. It was found when the carbon in comminuted form was contained in a porous cup, that the combination gave an E. M. F. of 1.24 volt, apparently due to the presence of the oxygen of the air.

It is impossible at the present stage of the investigation to assign any definite value of the E. M. F. to these forms of amorphous carbon. In some cases they appear to have an E. M. F. higher than that of graphite.

The energy of the combination of carbon and oxygen when completely oxidized to (CO_2) carbonic acid gas is stated to be 9624 foot-pounds per grain equivalent, which is 2.0594 equivolts.[3] In these carbon elements the E. M. F. is not so high, as there must be deducted the counter E. M. F. or polarization, and the energy due to the force of setting chlorine free.

A resort to chemical analysis, of the products formed by the reaction in the cell, indicates the following conclusions.

First—Carbon produced by the action of sulphuric acid on cane sugar proved to be partially oxidized, or impure carbon.

Analysis gave the following values:

C.	62.20	per cent.
H.	1.61	per cent.
O.	36.19	per cent.

Analysis proves that ($H_2SO_4 \times KClO_3$) sulphuric acid + chlorate of potassium oxidizes carbonaceous bodies, like the above product of (H_2SO_4) sulphuric acid on cane sugar, to CO_2, and further, that such bodies first are changed to compounds soluble in the acid (caramel-like substances), which are rapidly oxidized to CO_2.

Second—Battery carbon of the composition:

C.	96.20	per cent.
H_2O.	.70	per cent.
Iron, SO_3.	2.30	per cent.

The fact was shown that this form of carbon can be oxidized to CO_2.

Third—Wood charcoal, of the following composition after ignition:

C.	94.	per cent.
H_2O.	5.5	per cent.
Silicious res.	.5	per cent.

1. See *Q. Jour. Chemical Soc.*, vol. xii., October, 1859.

2. Great care must be taken in the preparation of this gas, as it explodes at a temperature of about 140 F. It can be preserved in the dark, and is decomposed by sunlight into its component parts.

3. See Sprague's *Electricity*, p. 519.

This, after repeated re-ignition, was oxidized by the electrolyte to CO_2, no intermediate compounds being formed, and further, in case of pure amorphous carbon the oxidation is complete; that is, that all the carbon is oxidized to CO_2.

These analyses were made with the solution at a temperature of 122 F. to hasten the action, the carbon being in contact with the platinum. In these elements the oxidizing material is too expensive for practical use.

Undoubtedly the direction of experiments in the future will be to find some cheap substance which will absorb oxygen from the air and give it up to the carbon; in fact, acting as a carrier of oxygen, so oxidizing it without heat; and this is not improbable, as we already know of subs ances which do this, though giving a low E. M. F.; thus, for instance, the ferric salts are reduced to ferrous by agitating their solutions with carbon, being regenerated by absorbing oxygen from the air.

By pursuing this line of investigation, we can be sure we are not ignorantly striving against any law of nature when attempting to convert the whole potential energy of carbon into electrical energy.

THE DEVELOPMENT OF THE MERCURIAL AIR PUMP.[1]

BY PROFESSOR SILVANUS P. THOMPSON, D. SC., B. A.

WITHIN the range of the physical sciences there are many subjects of interest to the investigator, some of them of importance in the technical industries, which yet are little known, save to the close student of scientific literature. An idea occurs to some original worker, who makes experiments, records results, draws inferences, and embodies his investigations in a memoir or note in the more or less obscure journal of proceedings of some scientific society, where it remains buried amid a heterogeneous mass of like matter. A few years later another worker, not knowing what has been done, stumbles across a similar idea, constructs his apparatus, makes his experiments and observations, and in turn consigns his work to a similar temporary oblivion. Years after, or it may be centuries, the progress of science in other departments reaches a point where it touches the unremembered work of those who are gone. Were that work available, were even a plain clue to its existence known, it would be at once brought into line and made useful. For want of such a clue it remains buried, and the world has to wait for some other to re-investigate what already was a portion of acquired knowledge; and the useful application to industrial purposes is delayed—perhaps for years. He who will explore the dusty corners of science, will hunt up the hidden treasures, arrange them, co-ordinate them with more recent knowledge, and render access to them easy for the busy workers around him, performs a service which, though it brings no renown, is at least useful.[2] In such dusty corners of science lie the scattered fragments of the literature of the mercurial air pump.

All true mercurial air pumps are, of course, based upon the principle of the barometer; that is to say, in all of them the vacuum is constituted in the manner invented by Torricelli, namely, in an enclosed space above a barometric column. In all of them the object is to render the Torricellian vacuum as perfect as possible. In some of them the object is effected by driving the air upwards out of the barometer head by raising the barometric column; in others, the air is forced downwards by the injection of more mercury into the barometer head. In others again, the air is pushed up one barometric column and down another. In some recent kinds of mercurial pump, several of these forms are combined. Other pumps again depend on the injection of mercury at high pressure through an orifice. These distinctions will furnish us with a basis for classification. Before attempting this, however, a few general historical notes may be given.

In 1643, Torricelli discovered the possibility of producing a vacuum above the top of a mercury column, by filling with mercury a tube closed at one end and then inverting it into a cup containing mercury. Until 1650—a period of seven years—when the mechanical air pump was invented by Von Guericke, there was no other way of producing a vacuum, and the Florentine academicians, who made in the interval many experiments on the properties of vacuous space, employed as their pump a Torricellian tube (figure 1) enlarged at its upper part into a bulb or reservoir closed at the summit by a cover, luted on with some suitable sort of cement. The apparatus is figured in Daguin's "Traité de Phisique," vol. 1, p. 278 (edition of 1855). Writing in 1855, Daguin states that though the employment of the vacuum obtained by the lowering of a mercury column had been perfected by Baader and by Hindenburg, their machines required such a large quantity of mercury that they had been abandoned in favor of the mechanical air pump. The Torricellian method of exhaustion was pursued, however, whenever a very perfect vacuum was required, for example, by Count Rumford,[3] in his researches upon the propagation of heat. The bulb to be exhausted he sealed to the top of a barometric tube having a constriction near the top; it was then filled with hot recently boiled mercury and inverted, when the mercury left the bulb vacuous. It was then sealed off before the blow pipe just as exhausted glow lamps are sealed off to-day. An arrangement almost identical with that of the Florentine Academicians was suggested as a novelty so late as 1810, by Traill.[4] In 1845, Edward A. King[5] patented the construction of an incandescent electric lamp, having a carbon pencil situated in the Torricellian vacuum at the upper end of a barometer tube, a further suggestion being made for sealing the exhausted lamp. Amongst still more recent methods of producing in a glow lamp a Torricellian vacuum without the aid of any specific pump, may be noted that of André,[6] who seals the lamp globe to the top of a barometric tube, another short tube opening into the bulb being sealed on above. Mercury is driven from below until it fills the lamp, when the upper tube is temporarily stopped, the mercury being then lowered, creating a vacuum into which the occluded gases are liberated; the mercury is then raised, and these gases

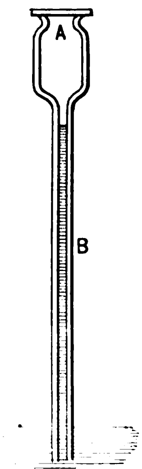

FIG. 1.—Tube Used by Florentine Academicians for Exhausting.

expelled through the stopper, and the lamp is sealed at the top; then the mercury is lowered and the lamp is sealed off at the bottom. Swinburne[7] has also tried this method, but has not found it successful. None of these processes of utilizing the Torricellian vacuum amounts to the invention of a distinct Torricellian air pump. Although most of the mercurial air pumps to be described started from the fundamental notion of producing a barometric vacuum, it seems possible, if not probable, that some, at least, of the various forms had a different origin. Two of the main defects of the ordinary mechanical air pump, are the faulty packing of the pistons and the unavoidable clearance space between the piston and the end of its cylinder. It naturally occurred to several experimenters, possibly to many, that both these defects might be obviated by covering the piston with a layer of mercury. Air pumps thus provided with a mercury packing have been described by Kravogl[8] for exhausting, and by Régnault[9] and Cailletet for compressing. In the following sketch, however, attention is confined to the barometric species of pump. It will be convenient to classify these machines under the following heads:—

CLASSIFICATION OF MERCURIAL AIR PUMPS.

1. Those which drive the air up a barometric tube.
2. Those which drive the air down a barometric tube.

1. Read before the Society of Arts, London (Eng.), Wednesday, Nov. 23, 1887.

2. The author here desires to express his indebtedness to the many friends who have assisted in collecting this information; also to the valuable paper by Herr E. Bessel-Hagen, referred to in the text. He also desires to refer to a memoir by Prof. Hellmann, of Riga, a copy of which he received only after the greater part of this paper was already compiled.

3. Rumford. Essays, vol. ii., p. 393. (Edition 1798.)

4. Traill. "Nicholson's Journal," xxi., pp 63 and 161.

5. King. Specification of Patent, No. 10,919, 1845.

6. André. Specification of Patent, No. 4,654, 1881. Electric Illumination, vol. i., p. 665.

7. See *Electrician*, xix., 159, July, 1887.

8. Kravogl. "Carl's Repertorium," iii., 362, 1868. See also Deschanel's "Natural Philosophy" (1881), i., 190. Similarly a mercury packing was employed in a water pump by Haskins, and is described in Desagulier's Course of Experimental Philosophy (1763), vol. ii., p. 491.

9. Regnault. "Rélation des Expériences," ii., 553.

3. Those which drive the air up one barometric tube and down another.
4. Combination pumps.
5. Injection pumps, dependent in their action upon the velocity of efflux of a stream of mercury.
6. Mechanical mercurial pumps.

Under the first three of these classes there are sub-classes comprising "shortened" pumps.

CLASS 1.—UPWARD DRIVING PUMPS.

The oldest of all mercurial air pumps belongs to the class in which the air is forced upwards above the top of a barometric column. It was invented by Emanuel Swedenborg, the famous theosophist, and is described in his "Miscellanea,"[1] published in 1722. The apparatus and a drawing of the machine is given, which is reproduced in figure 2. A glass receiver, B, stands upon a plate, A, as in the ordinary mechanical air pump, and the plate, A, is supported on three legs forming a tripod table. "Beneath this table," to follow Swedenborg's own words, "there is a certain conical vessel, E, of iron, hollow, and accurately fixed on the under side of the table so that it includes two apertures, *c* and *d*, furnished with valves." The valve *c*, opens downwards, the valve *d*, upwards. The lower end of the iron vessel ends in a flexible leather tube, *f f*, to which is adapted a piece of iron tube, *g g*, ending in an open mouth-piece, *m*. This iron tube was to be alternately raised and lowered precisely as is done in the modern Geissler or Toepler pump with the mercury vessel. Swedenborg's instructions are precise.

"OPERATIO.—Immitte mercurium vivum per (*m*), illa copia, ut repleat (*f*) (*f*) et aliqualem partem E; si dein sursum levas (*g*),

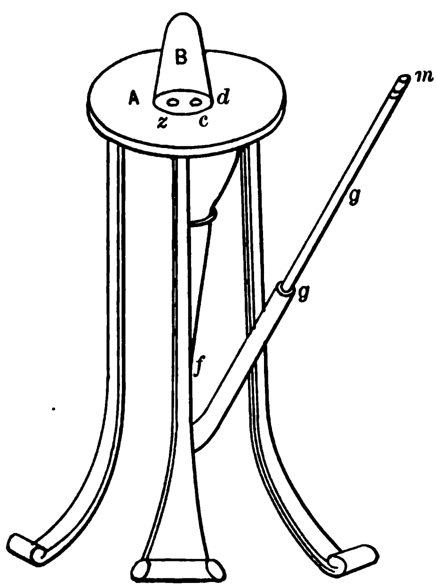

FIG. 2.—Swedenborg's Mercurial Air Pump.[2]

tunc mercurius ascendit in E usque ad mensulam: si dein demittis idem (*g*) infra altitudinem 28 pollicum, tunc descendit mercurius in E, attrahit secum aërem ex recipiente per valvulam (*d*), et sic levando et demittendo, dum omnis aër sit exantlatus. Habeas etiam foramen quoddam in (*z*) sub mensula, quod aperias ope trochleæ, et immittas aërem cum velis."

Further instructions say that the lifting must be continued until some drops of mercury come out at *d*. The nature of the valves, *c* and *d*, is not stated; they appear to have been such as were used in the current form of mechanical air pump.

In the above description and figure, Swedenborg's lettering is adhered to, but it may be convenient to state that in all the following cuts the lettering adopted is as follows:—

A.—The "pump-head" or hollow globe, which is filled and emptied.
B.—The barometric column or tube, also called the "shaft" of the pump.
b.—Barometric gauge.
D.—Drying apparatus.
E.—Eject tube or valve.
F.—"Fall tube."
G.—Gauge.
g.—The flexible lifting tube connecting S and B.
H.—Overhead tube.
J.—Mercury valve.
K.—Collecting chamber.
L.—Pressure chamber at bottom of shaft.
M.—Second chamber for partial vacuum.
N.—"Side tube."
P.—Piston.
p.—Plug of rubber.
R.—"Receiver."
r.—Regulating pinch cock.
S.—"Supply vessel," or reservoir of mercury.
s.—Rubber packing.
T.—Tap.
t.—Air trap.
U.—The valve opening inwards from the exhaust tube to the lower end of the pump head.

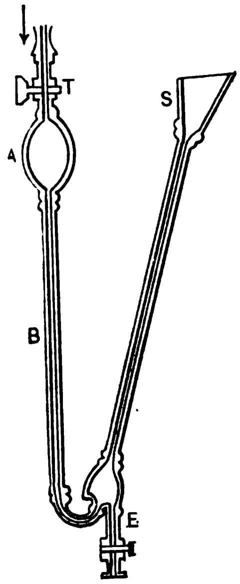

FIG. 3.—Baader's Pump. (First Form.)

V.—The valve opening outwards at the upper end of the pump head.
W.—Winch.
Y.—Three-way communication to atmosphere or auxiliary pump.
Z.—Return tube for mercury.

Sixty years elapsed before a second form of mercurial pump was devised, by Dr. Joseph Baader,[3] who, about 1784, devised the pump depicted in figure 3. This pump consisted of a hollow

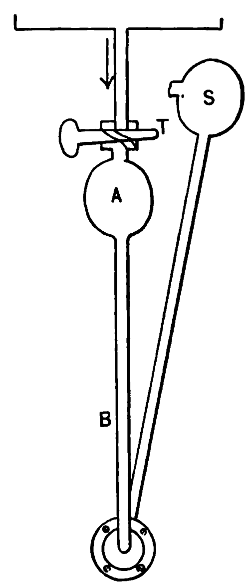

FIG. 4.—Baader's Pump. (Second Form.)

ellipsoidal vessel, A, at the summit of the barometric column, B, terminating above in a passage containing a three-way tap below it, bent round into a chamber with an outlet-tap, and having a second rigid tube, inclined at an angle, ending above in a funnel-shaped vessel to receive the mercury. To work this pump, the

1. Swedenborg. "Miscellanea observata circa res naturales, el praesertim circa mineralia, ignem, et montium strata." Lipsiæ, 1722, p. 101. See also "Gren's Journal," vol. iv., p. 407.

2. Swedenborg. "Miscellanea observata circa res naturales." Lipsiæ, 1722. Figure 11.

3. Baader. See Hübner's "Physikalisches Taschenbuch." Salzburg, 1784, p. 630, referred to in Gehler's "Physikalisches Wörterbuch," vi., p. 602 (ed. 1831).

bottom tap was closed, and the three-way tap was turned so as to make the pump head, A, communicate with the outer air. Mercury was then poured into S until A was filled; the three-way tap was then turned to cut off communication with the air, and to connect A with the receiver or other vessel to be exhausted. The bottom tap was then opened, and a portion of the mercury permitted to run out until the top of the barometric column was below A, producing a partial vacuum in the pump head and the receiver. The lower tap was then closed, the three-way tap returned to its former position, and the mercury which had flowed out of the pump was poured again into S, and the operation repeated. It will be obvious that this operation is equivalent to raising and lowering the supply vessel, as in the pumps of Geissler and Toepler, and their prototype of Swedenborg. Baader had a curious history. In 1784, when this pump was devised, he was studying in Vienna. He afterwards went to Göttingen, thence to Edinburgh, where he took the degree of Doctor of Medicine; but he quitted the medical profession for that of mining, and was afterwards connected with an iron works at Wigan. Gehler states that Baader abandoned his first form of pump in favor of a second,[1] shown in figure 4, which differs from figure 3 in

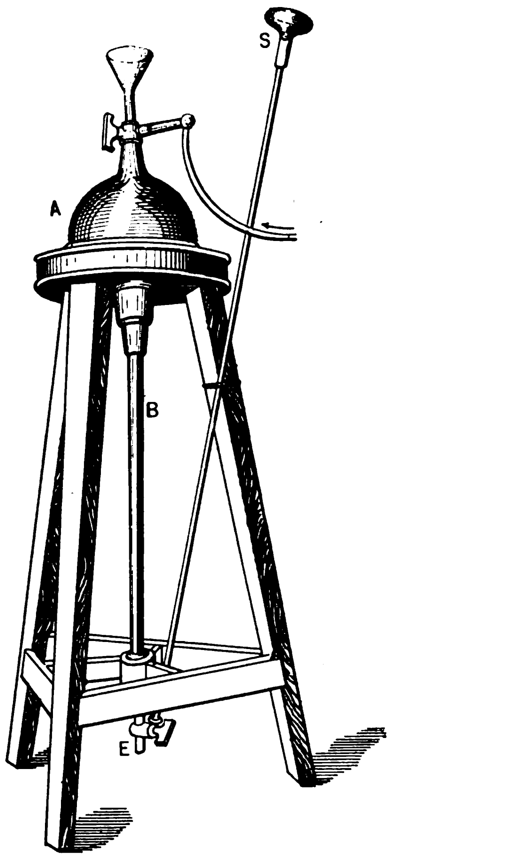

FIG. 5.—Pump in University College.

having the supply vessel capable of being raised and lowered, not by a flexible tube, but by turning it about on a joint provided at the meeting point of the barometric tube and the supply tube.

A very finely constructed pump, on Baader's principle, exists in the collection of apparatus in the physical laboratory of University College, London, having apparently been acquired in April 1828. There is no maker's name or date on the apparatus, but it belongs to, and is catalogued as being "the Torricellian part" of a fine double-barrelled air pump (price £100) by the famous instrument maker, John Cuthbertson, of Amsterdam and London. It is shown in figure 5. The exhaust pipe of brass leads from the three-way tap at the top to a union joint below the plate of the mechanical pump, so that the exhaustion having been carried in the ordinary way to a certain point, it should be completed by using the Torricellian part. The apparatus is mounted on a massive tripod of mahogany; the fittings of the taps are of metal (steel or iron); the height from floor to the top of the exit funnel is just under two meters; the height from the bottom tap to the bottom of the pump head is just over one meter. The barometric tube, B, is of glass, as is also the supply tube. The pump-head is a substantial glass vessel, almost exactly one meter in external circumference, hence it would require about 400 pounds of mercury to work the pump. Professor Carey-Foster states that it is believed to have been acquired by Dr. Lardner's direction; he has no knowledge of its having been used. I have not been able to discover in any of Cuthbertson's pamphlets or price catalogues now extant any reference to this part of the apparatus.

A pump on the same principle was patented in 1881 by Mr. Rankin Kennedy. It is described later.

In 1787, C. F. Hindenburg[2] described the pump shown in figure 6, closely resembling Baader's) but having a piston and cylinder for the purpose of driving the mercury up and down in the barometric tube.

Cazalet,[3] of Bordeaux, states in 1798, that he has constructed

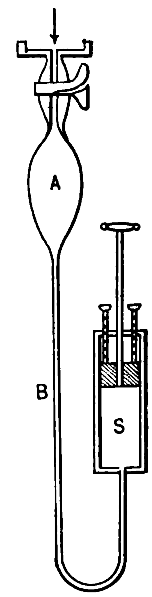

FIG. 6.—Hindenburg's Pump.

an apparatus like Hindenburg's, of glass and iron, and that he has succeeded with it in getting an exhaustion of one millionth of an atmosphere; how he measured this does not appear. A similar kind of pump appears to have been used by Michel.[4]

In 1804, A. N. Edelcrantz[5] published a "Description of a

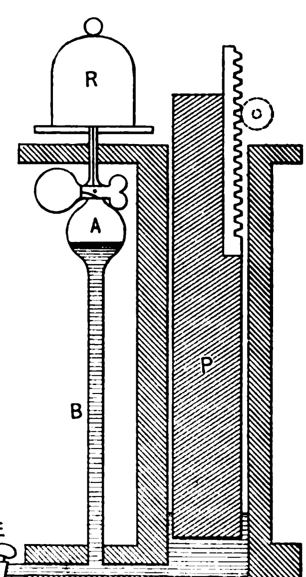

FIG. 7.—Edelcrantz's Pump.

mercurial air pump of unlimited exhausting power, with a wooden piston." This pump (figure 7), which appears to have

1. Baader. See Hübner's "Taschenbuch," cited above; referred to, with figure, in Gren's "Journal der Physik," ii., p. 326; see also Hindenburg. "De Antlia Baaderiana," 4to Leipzig. 1787, referred to in Young's "Lectures on Natural Philosophy." A quarto volume published at Bayreuth, in 1797, under the title "Theorie der Pumpen," is possibly by the same Baader.

2. Hindenburg. See Gehler's "Physikalishes Wörterbuch," vi., p. 603 (1831 edition), which refers to Hindenburg, "Antliæ novæ hydraulico-pneumaticæ mechanismus et descriptio." Leipzig, 4to., 1787. Young mentions also Hindenburg, "De Antlia Baaderiana." Leipzig, 4to., 1787; and to Hindenburg "De Antlia Nova," Leipzig, 4to., 1789.

3. Cazalet. "Gren's Journal," i., p. 478.

4. Michel. See "Gren's Journal," ii., p. 129.

5. Edelcrantz. "Nicholson's Journal." vii., p. 188.

been independently conceived, is on the same lines as Hindenburg's, but with superior mechanical arrangements. The three-way tap, instead of being bored diagonally toward the handle, is bored toward the outer end, as in the modern Geissler pumps, and the wooden piston, P, is moved in its stout wooden casing by a rack and pinion motion.

Some years after this "Nicholson's Journal" contains a description of Traill's[1] apparatus, which has already been mentioned. It drew a further communication from R. Bancks, instrument maker in the Strand, that he had constructed similar apparatus for Mr. Children at a prior date.

In 1824, Joseph H. Patten[2] wrote an "Account of a New Air-pump," which, like those of Hindenburg and Edelcrantz, had a piston to raise and lower the mercury, but which in another point more nearly resembled the original pump of Swedenborg. The pump-head consisted of a wide-mouthed glass globe, on the top of which was fixed a flat metal plate with a raised rim. In the centre of this was adapted a metal pipe, having a valve opening downwards below it. This valve, a mere metal plug, was held upon a stiff wire which entered the tube above, and was continued downward to the summit of the barometric tube, where it ended in a ball float. When the mercury rose it lifted the ball and closed the valve, and maintained it closed till it once more fell. The air in the pump-head was expelled through a separate valve, opening outward in another part of the plate. Patten suggested that instead of the stiff wire, ball, and valve, the exhaust tube should be prolonged downwards to near the bottom of the globe. The publication of this description drew from Professor J. F. Dana[3] some remarks suggesting, appar-

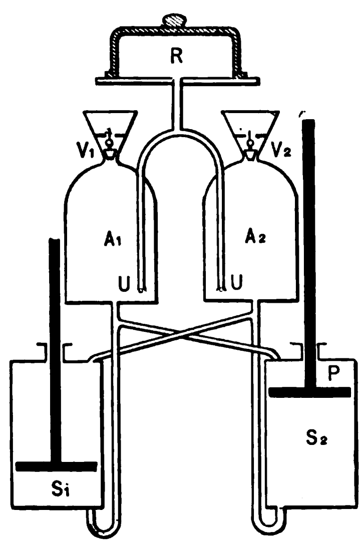

FIG. 8.—Kemp's Double-Acting Pump.

ently without knowledge of prior inventors, that it would be preferable to use a three-way tap. To this Patten replied in a later issue in a strongly personal vein.

A more complex form of pump, in which the mercury was moved by air pressure, applied by pouring mercury into a second vessel containing air—somewhat on the plan of Hero's fountain—was described in 1824 by Dr. E. Romershausen,[4] and in 1825 by Uthe.[5] In each case a complicated six-way tap was requisite.

In the same year a pump by Oechsle[6] was described, having a three-way tap connecting the pump-head alternately with the air and with the receiver to be exhausted, and provided also with a barometer gauge beneath the receiver. The mercury was lowered and raised, as in Edelcrantz's pump, by a large wooden piston, but worked by a chain and winch.

Next in strict historical order is the very remarkable pump of Mile, 1828, which, however, belongs to the third class of machines.

K. T. Kemp,[7] of Edinburgh, in 1830, designed a remarkable double-acting pump. In this machine a winch, manipulated like that of the ordinary mechanical air-pump, moves two pistons up and down in two cylinders, figure 8. These are full of mercury, which is thereby driven alternately into the two exhausting chambers, and which serve as pump-heads. They are provided with valves to admit air from the receiver, and also with valves opening outwardly to let out the expelled air. The latter pair of valves are ingeniously provided with floats, so that they close while there is still some mercury remaining above the actual valve to seal the joint and make it air-tight. The double pump of Gardiner, hereinafter described, closely resembles that of Kemp.

The year 1855 brings us to the famous pump of the late Dr.

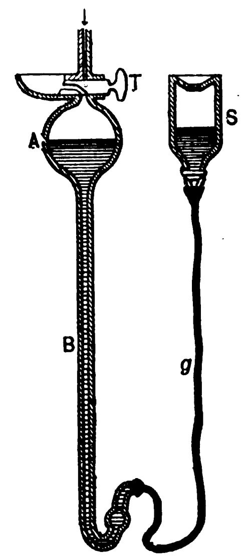

FIG. 9.—Geissler's Pump. (First Form.)

H. Geissler, of Bonn, which in his hands did such excellent work for exhausting the Geissler vacuum-tubes The first public mention of this pump appears to be in a pamphlet entitled, "Ueber das geschichtete elektrische Licht," published in Berlin, in 1858, by Dr. W. H. Theo. Meyer. As depicted in that pamphlet, the apparatus strikingly resembles the second form of Baader's pump. The form given by Geissler to this apparatus is shown in figure 9; which shows the vessel containing the supply of mercury, S, con-

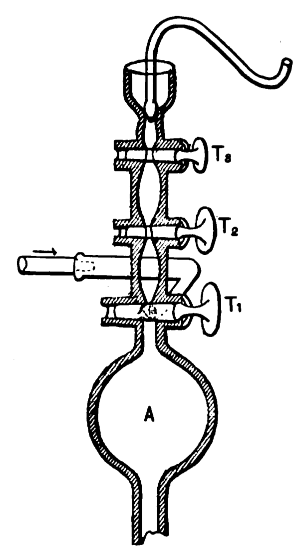

FIG. 10.—Geissler's Pump. (Recent Form.)

nected to the lower end of the barometric column, B, by a flexible India-rubber tube, g. The pump-head, A, is provided at the top with a large three-way tap, T. The operation of this simple contrivance is obvious; the air in the pump-head is repelled by raising the supply vessel, whilst the tap is in such a position that the pump-head communicates with the outer air. The tap is then turned so that the communication with the outer air is cut off, and communication is established with the vessel to be exhausted. This being done, the supply vessel is lowered down, when the

mercury in the pump-head sinks, and draws in air through the exhaust tube. The tap is then turned again, and the supply vessel is again raised to expel the air that has been drawn in, then the tap is turned and the supply vessel again lowered. By repeating these operations a sufficient number of times, the air remaining in the apparatus is reduced to a very small portion of its original amount, and the column of mercury in the tube, B, stands up to very nearly the height of the barometer. The perfection of the vacuum is limited by two causes: the inherent imperfection in the three-way tap, and the impossibility of expelling the film of air which adheres to the inner surface of the pump-head. However perfectly the tap may be ground into its seat, however carefully it is lubricated with stiff grease, still, air-films will remain between the working surfaces. There is a tendency for a channel to be formed in the film of grease at that part of the conical periphery of the tap where the apertures into it slide round against the internal wall of the glass seat; and through this channel in the glass, minute bubbles of air force their way. Moreover, the grease itself may give off vapors which spoil the perfection of the vacuum. The Geissler pump is, moreover, subject to other defects, amongst which may be enumerated the heavy labor of raising and lowering the supply vessel, the liability to accident to the glass top, the liability to fracture of the pump-head. The latter accident occurs not unfrequently, if, after a certain degree of exhaustion has been attained, the supply vessel is suddenly raised, for then, there being little or no air in the pump-head to serve as a cushion, the mercury rising in the pump-head strikes with a sudden blow against the upper portion of the pump-head and fractures it. The long barometric tube or shaft of the pump is also liable to fracture. The working of the

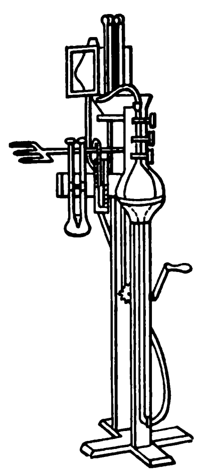

FIG. 11.—Geissler's Pump, (Complete.)

tap, being done by hand, requires continuous attention; lastly, the process of exhaustion is slow.

The subsequent improvements relate to the removal of one or other of these drawbacks. Some of them were introduced by Dr. Geissler himself, and by his successor, Herr F. Müller, of Bonn. The form depicted in figure 9 (taken from Toepler's paper in "Dingler's Polytechnisches Journal," clxiii., p. 426, 1862) shows the kind of three-way tap (a modification of Senguerd's) originally used, in which the passage for the expulsion of the air was carried through the conical body of the top to its end. In another form, the same kind of tap was used, but the exhaustion was made through this longitudinal passage, the external tubular seat being prolonged and connected with the vessel to be exhausted. In this case the air was expelled upwards through the transverse passage through the tap. In yet a third form the exhaust tube was sealed on at right angles to the external barrel, and the tap was pierced (on Babinet's plan) with a three-way transverse passage. In the most recent form given to the Geissler pump by its makers, there are three taps, one of them, a large one, being a three-way tap of the last mentioned kind, simplified by having only one transverse bore of conical form. The arrangements of this pump are shown in figure 10, in which T_1 is the three-way tap, and T_2 and T_3 plain taps of a smaller size. The use of the two upper taps is to enable the last traces of air to be more perfectly expelled from the pump-head. During the ordinary working of the pump the two top taps are always left open. After the exhaustion has reached a sufficient point, the large tap is turned so as to cut off communication with the exhaust tube, and to open communication from the pump-head upwards through all the taps. The supply vessel is then raised so high as to drive the mercury up above the level of the topmost tap. The top tap is then closed, and, by sinking the supply vessel, the mercury is caused to fall below the pump-head. It is then slowly raised, driving before it all the air that may remain in the pump-head, and collecting it just below the top tap. As soon as the mercury has risen through the second tap, this is then closed, and the mercury once more lowered. It will be seen that if the space between T_2 and T_3 is sufficiently great, this residual air will not become compressed to anything like atmospheric pressure, and hence the air-films forming in the upper part of the pump-head or in the channels of the three-way tap will be comparatively slight. The curved tube at the top is used for collecting the gases extracted in chemical operations; the horizontal exhaust tube is usually connected with drying vessels, and with

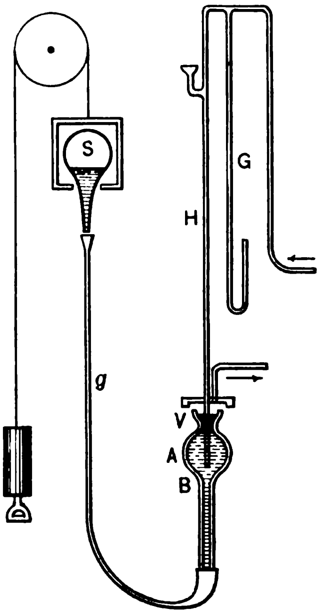

FIG. 12.—Joule's Pump.

appropriate gauges. The complete pump as used for the purposes of the chemical laboratory is shown in figure 11.

Morren's pump[1] is practically identical with Geissler's, save in a detail concerning the three-way tap, which has, instead of having a glass cone with a longitudinal passage pierced through it, a steel cone, with a channel or groove cut in the side. Another almost identical form was described by G. Jolly,[2] about the same

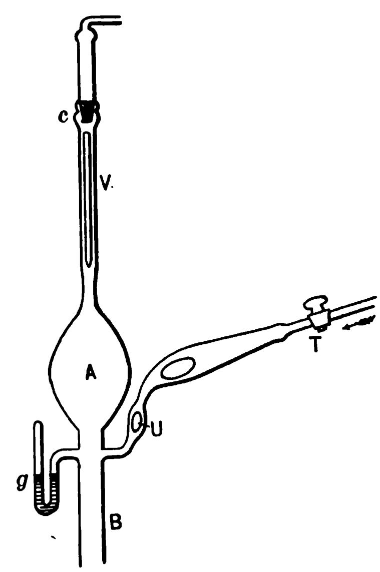

FIG. 13.—Mitscherlich's Pump.

time. It resembled Geissler's first form, but was provided with the mechanical device of a winch and pulley, to raise and lower the supply vessel. This device was speedily adopted by other makers; it may be seen in the latest form of Geissler's pumps. Jolly's pump also has a steel three-way tap. Von Babo[3] sought

to replace the egg-shaped pump-head by a glass cylinder, strongly held together between circular steel ends, and having two automatic valves opening into and out of it, precisely as in Kemp's pump of 1830 (figure 8). Poggendorff[1] further improved the mechanical lift by adding a counterpoise weight. Alvergniat[2] introduced an automatic valve into the exhaust tube, to prevent the mercury from being driven back into the exhausted vessel. Weinhold[3] modified the glass three-way tap, and added above it a small chamber, above which the opening into the outer air was closed by a second glass tap of similar construction. The use of this upper chamber to secure a more perfect vacuum brings this form almost into identity with Geissler's later form.

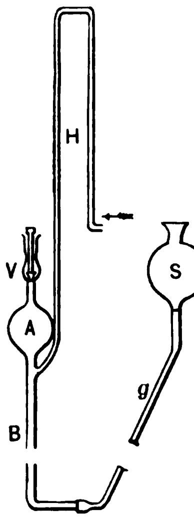

FIG. 14.—Lane-Fox's Pump.

The device of interposing such a chamber between the three-way tap and the external air was independently suggested in 1875 by Kundt and Warburg[4] and appears to have been already adopted by Geissler[5] in 1873.

In the years 1873 and 1874, Dr. Joule[6] devised several forms of mercurial pump, having but one valve, an India-rubber plug, V, fitting into a cone seat at the top of the pump-head, allowing the air to be expelled. A little mercury above it kept the joint secure. The necessity of emptying a second valve was obviated by the device (previously used by Mile) of connecting the vessel to be exhausted to the pump by means of an overhead tube, H, of more than barometric height which passed into the pump-head its open lower end descending nearly to the bottom of the chamber. This acted automatically as a trap; for, on the raising of the supply-vessel, the mercury rising in the pump-head first closed the orifice of the head-tube, so cutting off communication with the air that remained in the pump-head, but never rising in that tube to a height greater than 76 centimeters above the level of the valve. Another feature of Joule's pump was that the supply-vessel was closed at the top, being made of a globular flask. By allowing only a certain amount of air to enter this flask, the pressure inside was kept at less than atmospheric, enabling the length of the shaft, B, to be reduced. Later, a conical ground-glass tube was used in place of the India-rubber plug for a valve.

In 1873, Mitscherlich[7] altered the pump in the manner shown in figure 13. The double function performed by the three-way tap was in this form shared between an automatic valve, V, opening upwards only, and a plain glass tap, T, worked by hand. The valve consisted of a rod of glass, ground conical at its lower end, fitting into a tube of one centimeter internal diameter. This rod was raised from its seat by the mercury as it rose through the pump-head. A perforated cork placed in the eject tube above the valve prevented it from rising too high, otherwise it would, in falling, become jammed. The exhaust tube communicated with the pump through the tap, T, at a point below the pump-head; the communicating tube being enlarged to receive an hydrous phosphoric acid or other drying materials, the same being protected from the rising of the mercury by the interposition of a loosely-fitting glass valve of ovate shape, U.

7. Mitscherlich. "Pogg. Ann.," cl., 420, 1873.

Another modification, due to Lane-Fox,[8] is shown in figure 14. The valve at the top of the pump-head is a conical glass stopper ground to fit tightly into its seat, requiring to be removed and replaced by hand. The overhead tube, H, which acts as a barometric trap, is joined to the shaft of the pump just below the pump-head. Lane-Fox also suggested the use of an automatic valve (like that of Alvergniat) to obviate the necessity of using the tall head-tube. This pump was for a long time used by the Anglo-American Brush Electric Light Corporation for exhausting the Lane-Fox incandescence lamps; they introduced a number of modifications in detail, one of which consisted in replacing the stopper, V, by an automatic valve resembling Mitscherlich's. A side-tube leads from below the lower automatic valve, U, to the tap of the pump-head. There is also a spark gauge. A drawing of one of the intermediate forms of Lane-Fox pump is given in Gordon's *Electric Lighting* (1884), p. 83.

About the same date, minor improvements were suggested by several persons. Mr. Dew-Smith, of Cambridge, suggested the use, at the top of the pump-head, of an automatic valve consisting of a strip of rubber or silk stretched over an orifice, precisely as in many mechanical air pumps, the valve itself being surrounded by an upper mercury cup to ensure a tight joint. Messrs. Goebel and Kulenkamp,[9] who used an automatic glass valve to close the top of the pump-head, adopted above it a flexible tube, by means of which to return to the supply-vessel the small quantities of mercury which from time to time were driven up through the pump-head, with the ejected air. Guglielmo,[10] applying a very similar device, achieved the not unimportant result of causing the tap at the top of the pump-head to discharge the rejected residual air into a space already partially exhausted. This he accomplished by interposing in the flexible tube connecting the summit of the pump-head with the closed top of the supply vessel a vertical glass tube, about twenty centimeters long, with a three-way tap opening also into the air. Through this tap atmospheric pressure could be momentarily established when the supply-vessel was in its lower position, and nearly full of mercury. When it was raised, the mercury ran out of it into the pump-head, leaving the space in it partially exhausted; and into this vacuous space the three-way tap at the top of the pump-head opened to let out the ejected air. As will be seen later on, this device makes this pump resemble somewhat some pumps of the third group.

Mr. Albert Geissler[11] has replaced the three-way tap by two

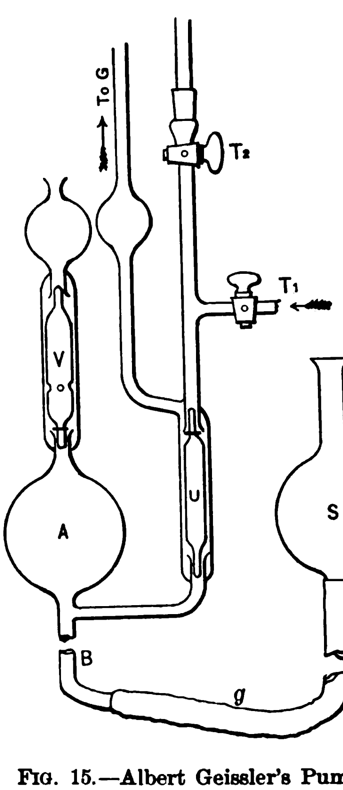

FIG. 15.—Albert Geissler's Pump.

automatic valves (figure 15, p. 30), one of which, V, opens from the top of the pump-head into the outer air; the other, U, admits air from the vessel to be exhausted into the pump just below the pump-head, as in the Mitscherlich and Lane-Fox pumps. These

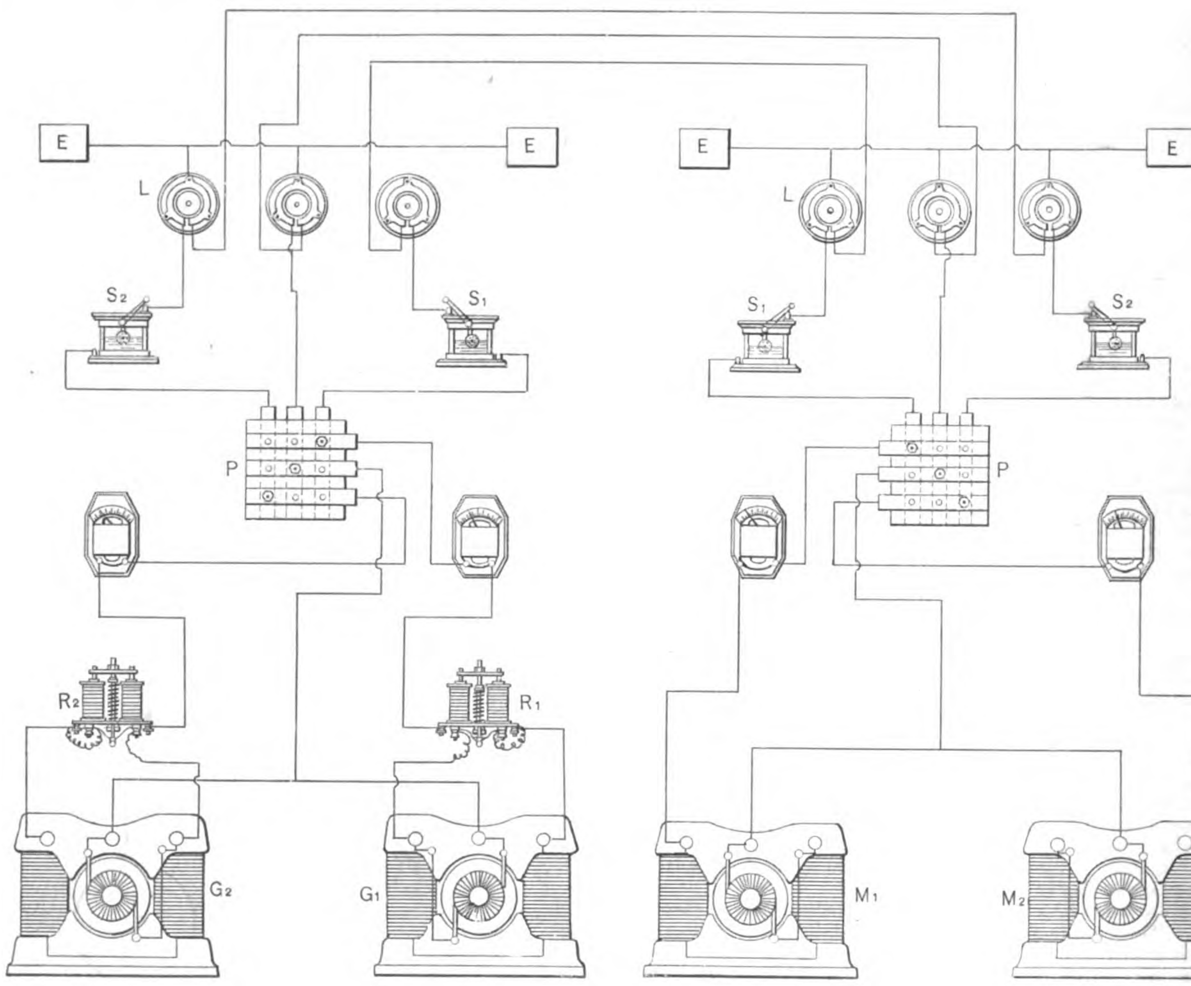
valves are hollow tubes of glass, with spindle ends to guide their motion, which float in the mercury when it reaches them. They are provided with accurately ground glass collars instead of conical ends, to fit against the ends of the tubes which they respectively close. An additional tap, T, is interposed for safety between the pump and the vessel to be exhausted. Other tubes lead to the manometric gauge and to the drying apparatus. This form of pump is intended for industrial use, where power is available to keep the supply-vessel slowly rising and sinking. A small improvement of recent date, due to Messrs. Greiner and Friedrichs,[1] consists of a new three-way tap of peculiar construction, pierced with two transverse channels at 45°. Of the three openings, two are at one side of the barrel, one at the other, so that the top has to be worked through 180° instead of 90°, and the channels in the grease do not lead directly from one aperture to another. Hence there is a lesser risk of leakage.

(To be continued.)

ELECTRIC TRANSMISSION OF ENERGY.

In our issue of the 8th of April, 1887, we gave an account of experiments carried out at the Oerlikon Engineering Works with a plant of two dynamos and two motors intended for the transmission of energy from Kriegstetten to Solothurn. These experiments were made by a committee of engineers and scientific men, with a view to ascertain the total commercial efficiency of the transmission plant; but as the machines were in this case placed side by side, the results could only be taken as approximately correct. It is evident that, in such an arrangement of machines and resistances erected within the limits of a covered workshop, the insulation of the circuits presents no difficulty whatever, whereas in the actual installation, when many miles of overhead wires must be used, the insulation becomes a matter of some difficulty, and atmospheric influences may also have some effect upon the performance of the plant. These considerations induced the makers to arrange for some further trials with the plant as actually installed. A committee was appointed, under the presidency of Professor Amsler, of Schaffhausen, the well-known inventor of the planimeter, and the following gentlemen were members: Professor Weber, of the Zürich Polytechnic School, and his two assistants; Professor Hagenbach Bischoff, of Basle; Professor Veith, who occupies the chair of machine construction at the Zürich Polytechnic School; Herr Keller, engineer to Messrs. Escherwyss, of Zürich; Herr Lang, a manufacturer of Derendigen, and Herr E. Bürgin, of Basle, the inventor of the Bürgin dynamo. This committee have just issued their official report on the trials made on the 11th and 12th of October last with the plant as actually installed. Before quoting the results of these trials, it will be well to briefly refer to the general arrangement of this installation. At Kriegstetten there is a water power available, representing about 40 actual horse-power, and the problem was to carry as much of this power as possible to a mill in Solothurn, the distance being four and three-fourths miles as the crow flies; but, allowing for deviations, the length of each circuit may be taken as about five miles. There are at Kriegstetten two generating dynamos, and at Solothurn two motors, coupled up on the three-wire system, as shown in the above illustration. A perspective view of the dynamo was given on page 358, vol. ii. Each dynamo weighs 3 tons 12 cwt., and has a Gramme armature 20 inches in diameter and 14 inches long, the normal speed being 700 revolutions per minute. Referring to the diagram of connections, G^1 and G^2 are the generators at Kriegstetten, and M^1 and M^2 are the motors at Solothurn. R^1 and R^2 are electro-magnetic switches which automatically come into action and short circuit the exciting coils in case of the current rising beyond a certain limit. This provision was introduced in order to guard against the destruction of the generator in case a short circuit should take place somewhere in the line. The current from each of the generators passes through an ammeter and then to a plug board, to which is also connected the balancing wire joining the negative brush of G^2 with the positive brush of G^1. The balancing wire is then carried direct to the middle one of the three lightning arresters, L, and then to the middle wire of the line, whilst each of the outside wires is led through a liquid switch, S^1 S^2, then to a lightning arrester, and to the line. Each lightning arrester consists of a circular metal disc, the edge of which is provided with projecting teeth, and situated in a concentric metal ring, the internal circumference of which is also provided with teeth, but not touching the teeth of the disc. All the discs are connected with a common earth wire and two earth plates, E E. Should a flash of lightning strike the line, the current



KRIEGSTETTEN. SOLOTHURN.

1. Greiner and Friedrichs. See "La Lumière Electrique," xxiii., 335, 1887.

will leap across the intervening space between the teeth of the ring and those of the disc, and will thus be led to earth without passing through the machinery. The same provision against lightning is made at the motor station. The switches s^1 s^2 are of peculiar construction, and consist of a vessel containing a conducting liquid and a perforated metal ball dipping into it. When the current is to be switched off, the handle is turned so as to raise the ball out of the liquid; but the circuit is not immediately interrupted since the liquid within the balls issues in fine streams out of the perforations, and so maintains the connection for a short time after switching off. As the liquid in the ball gets exhausted, and the streams become thinner, the resistance of the liquid connection is gradually increased to infinity, and thus causes the current to gradually diminish to zero. The line wires are supported on Johnson & Philips' patent fluid insulators, and the average span is about 130 feet. Two sets of experiments were made. On the 11th October only one generator and one motor were tested, whilst on the 12th October both generators and both motors were tested. In the latter test the balancing wire was cut out of circuit as of no importance when, as in these experiments, it was quite easy to regulate the load of each motor so as to fairly divide the work between them.

Electrical measuring instruments were fitted up at both stations in rooms sufficiently distant from the machinery, so as not to be influenced by stray magnetism. The current was measured by large tangent galvanometers, and Thomson mirror galvanometers, standard cells, and potentiometers were used to measure the pressure. The object in measuring the current at both ends of the line was to ascertain whether any appreciable leak took place. In addition to these purely electrical measurements, observations were made at the generator station regarding the water level in the head and tail race of the turbine, the position of the regulator on the latter, and the speed of the dynamos and turbine. After the transmission trial on the 11th October was completed, the armature of the dynamo was taken out and replaced by a plain spindle provided at the end with a brake. The turbine was then started again under exactly the same conditions as were noted at the previous trial, and the power absorbed by the brake was measured. The comparison between the power thus measured and the electrical energy given out by the generator is evidently the commercial efficiency of the latter. On the following day both generators and both motors were tested in the same condition as prevails in actual practice, with the only exception that, as already mentioned, the balancing wire was cut out of circuit. This alteration, which could obviously not increase the efficiency of the whole system, was made to simplify the measurements. The power absorbed by the generators was computed on the basis of the previous day's trial from the observed conditions under which the turbine worked, whilst the power developed by the motors was on both days directly ascertained by means of a friction brake fitted to a first motion shaft common to both motors. A small correction was made for the power absorbed by this shaft when running idle. The following tables give the results as published by the committee:—

I.—Electrical Measurements.

Time of trial.	Electromotive force.		Terminal pressure.		Current measured at	
	Generators.	Motors.	Generators.	Motors.	Generators.	Motors.

" "	91.6	91.4	88.7	88.2	74.6	

An inspection of these figures will show that there is practically no loss of current by leakage on the line. In some cases the current measured at the motor station is slightly below that measured at the generator station; but the discrepancy is exceedingly small, and evidently due to personal or instrument errors, since in some other cases the current received by the motors appears to be even slightly larger than that sent out by the generators, which is obviously impossible. The second table also shows the influence of the air temperature upon the total resistance. The third table gives the power, and the fourth the efficiencies in percentages. It will be noticed that when one generator and one motor only were used, the commercial efficiency was slightly over 68 per cent.; but when both generators and both motors were used, this efficiency rose to about 75 per cent., which is clearly due to the higher voltage employed. On the whole, the result of these trials must be considered highly satisfactory, and Mr. C. E. L. Brown can be congratulated upon having succeeded in transmitting power over a distance of five miles with a loss not exceeding 25 per cent. It is needless to say that so high an efficiency could not possibly have been attained with any purely mechanical system of transmission.—*Industries.*

A NEW FORM OF SECONDARY BATTERY.[1]

BY KILLINGWORTH HEDGES.

(Mem. Inst. Civil Engineers.)

Secondary batteries or accumulators may be said to have become a necessity in private installations of the electric light, and to be as far advanced as any other part of the lighting system. The batteries which are best known are widely different from those designed by the original inventor, M. Gustave Planté, very little attention having been paid to this type until the matter was taken in hand by a French engineer, M. Phillimond Bailly, whose invention I shall have the honor of describing to you to-day. The battery, which has been termed the Phœnix, is of two kinds, Pb-Pb or lead-lead, and Pb Zn or lead-zinc, and it is to the latter to which I will confine my remarks. The idea of using zinc for the cathode or positive plate of a secondary battery is not new in principle, having been described by several inventors, but its adoption for commercial work was not practicable until about a year ago, when M. Bailly introduced this battery in several installations abroad, where they are still employed. M. Reynier had previously designed a battery with a lead or copper plate coated with zinc, but it failed, and long before this Mr. Swinburne tried a similar plan, employing oxide of carbonate of zinc; but both these arrangements were far more expensive than that of M. Bailly, who prepares his zincs by moulding zinc filings with mercury, and compressing it into a rod or plate.

In a lead-zinc battery the action is as follows:—The zinc plate is attacked by the sulphuric acid in the presence of the peroxide of lead, the latter acting as a perfect depolarizer; consequently the reaction is much more energetic than in a lead-lead battery, and the available E. M. F. is, in fact, 2.5 volts, falling to 2.33 when current is taken out. A lead-zinc accumulator is, in fact, a perfect primary battery, in addition to having a large storage capacity, which M. Bailly has found to be five times as much as a lead-lead battery with plates of similar surface. In discharging the zinc plate dissolves in the dilute acid, forming sulphate of zinc, which is decomposed on re-charging, pure metallic zinc being deposited on the zinc plate. The zinc, if properly amalgamated, is thus never consumed, but only dissolved and re-deposited. I have on the table some zinc plates which have been used in a small portable battery which I have used nearly every evening for the past four months, and they are still quite fit for work, although they are simple strips of commercial zinc, and not made on M. Bailly's plan of moulded filings. If the latter is employed I do not see why the zinc plate should not last as long as the peroxide plate. The lead plates of the Planté cell were simple sheets of rolled up lead, and had very little capacity. In the Phœnix battery they are formed of a quantity of fine shreds termed "lead wool" which are interwoven among a number of

1. Paper read before the British Association Meeting at Manchester (Eng.), September, 1887.

strips or fringes cut out of a lead plate, so as to form a sort of basket work, which is submitted to pressure, and then placed in the space left between a porous pot and the outside receptacle. The object has been to have a solid metallic conductor permeating the whole mass of the lead wool, so as to pick up the current with a minimum loss due to internal resistance, which has been the cause of failure of those Planté batteries in which lead wool or spongy lead was employed. M. Bailly compares his mode of picking up the current to the "venous system of the human body," in that the main conductor or artery spreads out in every direction much in the same manner as the veins in the body. The capacity of lead plates constructed in this manner is very large, the lead wool giving a surface of 1.5 square meter per kilogramme of lead; every part of the mass is permeated by the fringe-like extensions of the conductor, which being of much larger section than the lead wool filaments remain firm and solid when the latter are completely peroxidized.

Lead-zinc batteries may be constructed in various forms; a convenient arrangement is the circular form which I designed with a view to strength and portability.

The zinc plate is contained in a circular porous pot, conical at the bottom so as to economize the mercury, which forms an excellent electrical connection between the copper conductors and the zinc, without the use of a soldered joint, and admits of the speedy removal of the zinc plate. In larger cells a flat zinc electrode is used, and is contained between two porous plates which are made of compressed sand and offer very little resistance to the current, because they are honeycombed in every direction, and are, in fact, too porous for primary batteries.

The outside case is made of celluloid, a material which is extremely useful for electrical purposes, in that it is unaffected by acid and can be readily moulded into any required shape; also it is much lighter than any other suitable material. For small cells I usually protect the celluloid by a wicker-work covering, but in larger kind, when they have to be removed for charging, a very light and strong receptacle is made by placing the celluloid in a loose fitting wooden box, and running an insulating material between the two, which effectually takes off any jar that might injure the interior cell. I have found that the most suitable material is a compound known as Phoenix varnish, in that it is almost as cheap as pitch and does not shrink or crack at a low temperature.

A disadvantage attending the use of a lead-zinc battery has been often quoted, namely, that there is a greater fall of electromotive force than with a lead-lead couple. This is not a serious objection, even for lighting purposes, if the discharge is not pushed too rapidly; for driving motors, electrical welding, and other new methods to which secondary batteries may be applied, a fall of electromotive force is of little consequence, and is more than compensated for by the gain of nearly 25 per cent. in the E.M.F. M. Bailly states that he has obtained an output of nearly five times as much from a lead-zinc battery of similar surface to a lead-lead without lowering the E M. F. below two volts; he has also obtained 28 ampere-hours per kilogramme of peroxidized plate, or 0.08lb. per ampere-hour. In practice I have not obtained so good a result, the average output being 0.13 lb. per ampere-hour, which, however, compares very favorably with other batteries.

In the early days of accumulators it was seriously proposed to distribute electricity by their use in the same manner as milk. The all-important factor of the difference in weight of the empty milk cans—as compared with the empty batteries—was apparently forgotten, and the public quickly found this out, although there is a story that a railway company were satisfied with this statement that a set of batteries were empty, and, therefore charged the carriage at the returned empty rate.

It would not, however, be practicable for a few people living in the neighborhood to arrange to take a supply of electricity for lighting their principal rooms, as a small set of batteries on the plan I have here could be easily delivered.

This basket contains six cells or bottles, the total weight being under 1 cwt., so that the whole can be carried by one man. The capacity of each cell is 60 ampere-hours, and a sufficient number of lamps can be maintained to light a dinner table.

There is a great want at the present time for a small portable battery for railway carriage lighting, to be used as a reservoir for maintaining the lamps when the carriages are uncoupled for the purpose of making up the train. The successful illumination of railway trains by electricity has been practically demonstrated by the North-Western and other companies, which have had trains electrically lighted for some years. The plan which appears to give the best results is to fix a small dynamo and high-speed engine either on the locomotive or back of the tender, giving the driver control of the apparatus, so that he can readily start it from the foot plate. The only objection has been the impossibility of disconnecting the carriages without extinguishing the light. A battery on the plan I have described would not occupy more space than the receiver which is usually employed with the oil gas system, and would be far safer in every way.

The immunity from accident on our well managed railways is probably the reason that some fearful disaster has not before this attended the use of compressed gas. Railway passengers are ignorant of the dangerous nature of the illuminant, which is generally stored in steel cylinders under the carriages, although these cylinders are amply strong enough to resist the enormous pressure of the gas, but would be easily perforated in the event of a collision, with the result that the liberated gas mixing with air would either explode or, in all human probability, cause a dangerous fire.

If such an accident occurred in a tunnel—for instance, on the underground railway, where the system is generally adopted—there is the additional danger of suffocation from the escaping gas, which would occupy a very large volume of space. An accident took place quite recently on the Berlin Potsdam railway which ought to act as a warning. An empty goods train ran into a passenger train, piercing the gas cylinder. The liberated gas, being set on fire by the goods engine, flew about in all directions, setting fire to everything in the carriage, in which there were three persons, who, before they could escape, were burnt to cinders. It is stated in the official account that the only remnant of the male passenger was "the buttons on his waistcoat." The gas receiver was a long sheet iron drum placed transversely under a second-class carriage.

It is needless to say that with electric light no such accident could happen, and as the employment of the compressed gas appears to offer the chance of either "cremation or suffocation," it would be far better for the railway companies to improve their existing oil lamp system until they can see their way to universally adopt the electric light.

REVISION OF THE PATENT LAW.[1]

BY C. A. BROWN.

THE business in which most of us are engaged, viz., that allied in some way to the manufacture and introduction of electrical apparatus, touches the law at many points. First, there is the patent law which prohibits the manufacture, sale or use of apparatus infringing on the monopoly given by the government to the patentee of anything new and useful. Then after you have made something which you are willing to guarantee is no infringement on any man's patent—no matter what some competitor may say—you meet, besides the laws relating to contracts, the more complicated questions regarding the powers of city authorities, perhaps, and last of all when you have made your apparatus, secured your contract in the proper form, and installed your plant, you meet the laws framed, so it is said, to enable people to avoid paying their just debts. We shall surely not go amiss then, if for one evening we turn from the consideration of mechanical electrical contrivances to discuss interests less physical in their character.

The subject which will be briefly presented in this paper is the patent law and its proposed amendment. Special interest attaches to this subject just now, as you are all aware, because an effort is being made, backed by the authority of the National Electric Light Association, to have a patent commission established. At the approaching electric light convention an effort will doubtless be made to take some final action in this matter, and it is in part with the view of having such of our members as shall attend this convention prepared to take intelligent action on this question that this paper on this subject is presented.

The bill which will be introduced into the fiftieth Congress and to assist in securing the passage of which we have all been or will be asked to contribute, is as follows:

A BILL CREATING A COMMISSION TO EXAMINE AND REPORT TO CONGRESS NEEDFUL REFORMS IN THE PATENT LAW.

"*Whereas*, The patent laws of the United States are deemed to be in such condition as to require revision; therefore,

"*Be it enacted*, by the Senate and House of Representatives of the United States in Congress assembled:

"Section 1. That a commission be, and the same is hereby created, to consist of three suitable persons to be appointed by the President of the United States, who shall hold office until a final report of this commission is submitted to and accepted by Congress, and who shall receive for their service a compensation of $5,000 each per annum.

"Sec. 2. It shall be the duty of this commission to examine thoroughly the patent laws of the United States, and those of other countries, and their practical operation and effect, in meeting the needs of the public and fulfilling the purposes for which they were created; to formulate a report to be submitted to Congress which shall set forth the results of this investigation and their conclusions therefrom, with reference to changes in, or additions to, the present law pertaining to patents. The report shall also contain a draft of an act which will provide for the changes found necessary by the investigations of the commission.

"Sec. 3. The commission is authorized to employ such clerical force as may be necessary for the proper conduct of its work and to incur such other expenses for stationery, printing, etc., as may be found expedient.

"Sec. 4. The salaries of the members of this commission as

1. Read before the Chicago Electric Club, January 16, 1888.

well as all expenses legitimately incident to its work, shall be paid from the surplus in the United States treasury to the credit of the patent office. All expenditures by or for said commission, other than the salaries of the members, shall, however, be under the control of and authorized by the Secretary of the Interior."

When this bill is introduced into the fiftieth Congress is it not likely that some congressman will ask, "If some one knows that the patent law needs revision why doesn't he point out in what respect the revision is necessary?" If this congressman should be "a terrible granger from the west," to use an expression of Mr. Walker in his speech at a recent meeting of the American Institute of Electrical Engineers, will he not go on and exclaim, "Fifteen thousand dollars a year and expenses to investigate the English and French, the German and Russian, the Swiss and Dutch patent laws and their practical operation!" (We are all aware that patent laws in Switzerland and Holland are like snakes in Ireland—there aren't any.) He will ask further, "Why can't we use the investigations which have already been made and the reports which have already been rendered about the foreign patent systems? Such reports are found in numerous books." And then he may assert that this commission scheme is a device of protectionists to reduce the surplus without reducing the tariff, and thus will be blighted the hope of those who favor this bill on the ground that it will allay the suspicions of Congress as to the ulterior motives of its promoters. It may seem to some misguided granger that the advocacy of a bill proposing three $5,000-a-year jobs is in itself proof of an ulterior motive.

There is no dispute as to the advisability of a revision of the patent law in some respects. Mr. Steuart and others have pointed out numerous features which require change. Some of the faults that are found with the law are rather fanciful, but whatever they are can anyone say that it would be more difficult to have them remedied by applying directly to Congress than it would be for instance, to secure the enactment of the proposed law creating a commission? And then we have to take the risk of the commission not being able to accomplish any good, and the possibility that the commission may consist of men who will do the patent law more harm than good.

Without claiming that we have "nothing to do with abroad," with entire willingness to learn whatever may be learned from foreign patent systems, and with due acknowledgment of the fact that the patent law of the United States is the offspring of the system of Great Britain, we can justly claim that our patent system is superior to that of any other country, both theoretically and practically, and a glance at the history of our patent law will show that it is not impossible, even without the aid of a commission, to amend it as occasion requires.

The constitutional provision for patents is contained in Article I., Section 8, of the fundamental law of the nation: "The Congress shall have power to promote the progress of science and the useful arts by securing for limited times, to authors and inventors, the exclusive right to their respective writings and discoveries."

The first patent law, which was approved April 10, 1790, and has been amended and changed many times since without radical departure from the system originally founded, prescribed a petition to the secretary of state, the secretary of war and the attorney-general and demanded a fee of five dollars. February 21, 1793, the act of 1790 was repealed and a new one was passed permitting the merger of existing state grants in regular national patents, and raising the fee to $30. By act of July 4, 1836, the patent office and the office of commissioner of patents were created; patents ran for 14 years, conditionally extensible for seven more; provision was made for examination into the novelty of the alleged invention; the fee for citizens was kept at $30 with a drawback of $20 if the patent was not allowed. The act of August 29, 1842, made designs patentable. The act of March 2, 1861, abolished extensions and made the term of patents 17 years; the application fee was made $15, and the final fee $20. Later acts are substantially codifications of the act of 1861, as modified by the construction which courts have put upon it.

In the discussion, at a recent meeting of the American Institute of Electrical Engineers, in New York, of the question of the expediency of agitating patent law revision now, in view of the hostility to the patent system which might be brought into active exercise, Mr. Phelps gave expression to the foreboding that an effort might be made to sweep away the entire patent system. George Ticknor Curtis asked if it would not be necessary to strike out part of the constitution to reach that? Mr. Phelps very cleverly and acutely replied by asking Mr. Curtis if the provision in the constitution were not that Congress *may*.

This question of Mr. Phelps brings out very clearly a point that is worthy of careful attention, viz., the reason, as presented in the language of the constitution, why patents are granted. These reasons are not the ones that popular understanding supposes them to be. The belief is general that inventors have a natural right to the exclusive use of their inventions, and that the chief end and aim of the law is to give reward to the inventors. Such is not the case; an inventor has no natural right to the exclusive use of his invention. As a learned judge has said: "An inventor has no right to his invention at common law. He has no right of property in it originally. The right he derives is a creature of the statute and of grant, and is subject to certain conditions incorporated in the statutes and in the grants. If to-day you should invent an art, a process or a machine, you have no right at common law, nor any absolute natural right, to that for seven, ten, fourteen, or any given number of years against him who invents it to-morrow, without any knowledge of your invention, and thus cut me and everybody else off from the right to do to-morrow what you have done to-day. There is no absolute or natural right at common law, that I, being the original and first inventor to-day, have to prevent you and everybody else from inventing and using to-morrow or next day the same thing.

"If an inventor has a natural exclusive right for his invention for one moment, he has it forever; and if any limit of time can be set to such a right, only infinite wisdom is adequate to the task. To state the doctrine of natural right thus is to show that it does not exist. The law has never recognized the doctrine of natural right for it can not recognize what does not exist.

"The constitution of these United States gives Congress power to enact laws for a definite purpose, which is 'to promote the progress of science and the useful arts,' and the means to be used are, 'by securing for limited terms to authors and inventors the exclusive right to their respective writings and discoveries.'"

The reason for enacting patent statutes is clearly stated in the fundamental law, but I submit that there is nothing in this fundamental law that renders it imperative on Congress to enact patent statutes, or to prevent Congress from sweeping away at once, constitutionally, all patent statutes that have been enacted. The safeguards of the present system are its wisdom and beneficent results.

It is estimated that at present one-half of the important inventions the world over originate in the United States. The records of our Patent Office are sought for and studied by the inventors and scientists of every nation, and the wisdom of our advanced policy is almost universally admitted by men of the best intelligence. Sir William Thomson said in 1876, "If Europe does not amend its patent laws, America will speedily become the nursery of important inventions for the world."

Generally speaking, foreign patent systems differ from the American in not requiring an exhaustive preliminary examination of the invention as to novelty and utility before issuing the patent, in collecting annual taxes on patents, and in requiring the invention to be worked within a given period.

I have gone briefly and cursorily into the history and policy of our patent system to show that it is the product of wisdom and the result of mature and deliberate consideration. It can be improved, but not by any ill-considered action, and it is to be hoped that wise counsel will prevail when this subject is under consideration by the National Electric Light Association. Some of the reasons why the proposed bill should not receive the final sanction of that body are:

First.—The unnecessary risk of having a commission which may be composed of men ignorant of or inimical to the present patent system.

Second.—The questionable policy of agitating patent law reform at this time when there is undoubtedly a good deal of hostility to the patent system on account of the driven well patent, the barb wire fence patent, and other patents.

Third.—The difficulty of getting the question of patent law reform properly considered during the term of Congress just preceding a national election.

Fourth.—The questionable policy of going indirectly about accomplishing the reforms which are desirable, instead of appealing directly to Congress to pass such amendments as are agreed upon as necessary and proper.

Fifth.—The advisability of getting a better general knowledge among those interested, of the present system, its merits and defects, before asking that they take action in amending the system.

Sixth.—The fact that many of the wisest and most thoughtful of patent lawyers and others well versed in the patent law and its operations, are opposed to the presentation of the bill referred to. I hold that no action of this sort should be taken without practical unanimity of the members of the body which is asked to give its authority and influence to the measure.

SPECIFIC INDUCTIVE CAPACITY.[1]

BY J. HOPKINSON, M. A., D. SC., F. R. S.

THE experiments which are the subject of the present communication were originally undertaken with a view to ascertaining whether or not various methods of determination would give the same values to the specific inductive capacities of dielectrics. The programme was subsequently narrowed, as there appeared to be no evidence of serious discrepancy by existing methods.

In most cases the method of experiment has been a modification of the method proposed by Professor Maxwell, and employed by Mr. Gordon. The only vice in Mr. Gordon's employment of that

1. Read before the Royal Society on Thursday, November 17, 1887.

method was that plates of dielectrics of dimensions comparable with their thickness were regarded as of infinite area, and thus an error of unexpectedly great magnitude was introduced.

For determining the capacity of liquids, the apparatus consisted of a combination of four air condensers. with a fifth for containing the liquid arranged as in a Wheatstone bridge, figure 1. Two, E F, were of determinate and approximately equal capacity, the other two, J I, were adjustable slides, the capacity of either condenser being varied by the sliding part. The outer coatings of the condensers E F, were connected to the case of the quadrant electrometer, and to one pole of the induction coil, the outer coatings of the other pair, J I, were connected to the needle of the electrometer and to the other pole of the induction coil. The inner coatings of the condensers J F were connected to one quadrant, and I E to the other quadrant of the electrometer.

The slide of one or both condensers, J I, was adjusted till upon exciting the induction coil no deflection was observed on the electrometer. A dummy was provided with the fluid condenser, as in my former experiments, to represent the necessary supports and connections outside of the liquid. Let now x be the reading of the sliding condenser when no condenser for fluid is introduced, and a balance is obtained. Let y be its reading when the condenser is introduced fitted with its dummy, z, when the full condenser is charged with air. Let z_1 be the reading when the condenser charged with fluid is introduced, then will K, the specific inductive capacity of the liquid, be equal to $(y - z_1)\ 1\ (y - z)$.

Three fluid condensers were employed, one was the same as in my former experiments.[1] Another was a smaller one of the same type arranged simply to contain a smaller quantity of fluid. The third was of a different type, designed to prove that by no chance did anything depend on the type of condenser; this done it was laid aside as more complicated in use.

To determine the capacity of a solid, the guard-ring condenser

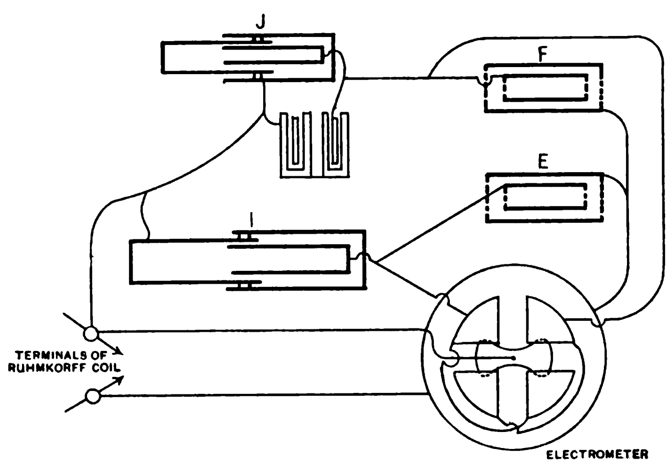

Fig.1.

of my previous experiments[2] was used. Advantage was taken of the fact that at the time when there is a balance the potentials of the interiors of all the condensers are the same. Let the ring, O, of the guard-ring condenser be in all cases connected to J, let the inner plate of the guard ring be connected to J, as in figure 2, and let a balance be obtained. Let the inner plate be now transferred to I, as in figure 3, and again let a balance be obtained; the difference of the two readings on the slide represents on a certain arbitrary scale the capacity of the guard-ring condenser at its then distance.

In some cases it was necessary to adjust both condensers to obtain a balance, then the value of a movement of the scale of one condenser in terms of the other was known from previous experiment. In some cases it was found most convenient to introduce a condenser of capacity known in divisions of the scale of the sliding condenser coupled as forming part of the condenser J. The old method of adding the opposite charges of two condensers, then connecting to the electrometer and adjusting until the electrometer remained undisturbed was occasionally used as a check; it was found to give substantially the same results as the method here described when the substance was insulated sufficiently well to give any results at all.

Colza Oil.—This oil had been found not to insulate sufficiently well for a test by the method of my former paper. Most samples, however, were sufficiently insulating for the present method. Seven samples were tested with the following mean results :—

No. 1. This oil was kindly procured direct from Italy for these experiments by Mr. J. C. Field, and was tested as supplied to me—

K = 3.10.

No. 2 was purchased from Mr. Sugg, and tested as supplied—

K = 3.14.

No. 3 was purchased from Messrs. Griffin, and was dried over anhydrous copper sulphate—

K = 3.23.

No. 4 was refined rape oil purchased from Messrs. Pinchin and Johnson, and tested as supplied—

K = 3.08.

No. 5 was the same oil as No. 4, but dried over anhydrous copper sulphate—

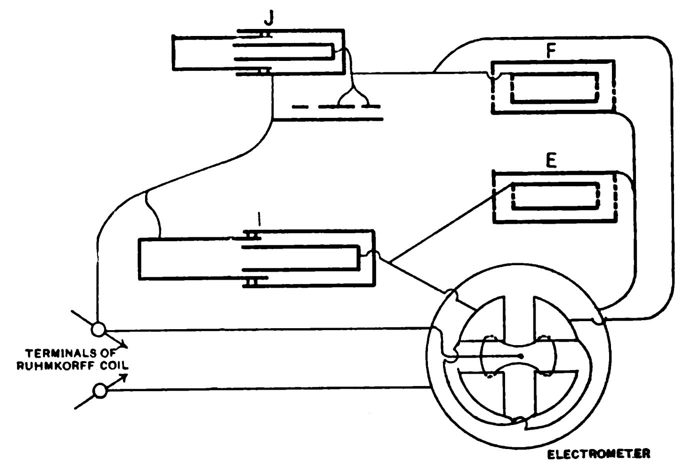

Fig.2.

K 3.07.

No. 6 was unrefined rape purchased from Messrs. Pinchin and Johnson, and tested as supplied, the insulation being bad, but still not so bad as to prevent testing—

K = 3.12.

No. 7. The same oil dried over sulphate of copper—

K = 3.09.

Omitting No. 3, which I cannot indeed say of my own knowledge was pure colza oil at all, we may, I think, conclude that the specific inductive capacity of colza oil lies between 3.07 and 3.14.

Professor Quincke gives 2.385 for the method of attraction between the plates of a condenser, 3.296 for the method of lateral compression of a bubble of gas. Palaz[3] gives 3.027.

Olive Oil.—The sample was supplied me by Mr. J. C. Field—

K = 3.15.

The result I obtained by another method in 1880 was 3.16.

Two other oils were supplied to me by Mr. J. C. Field.

Arachide.—K = 3.17.

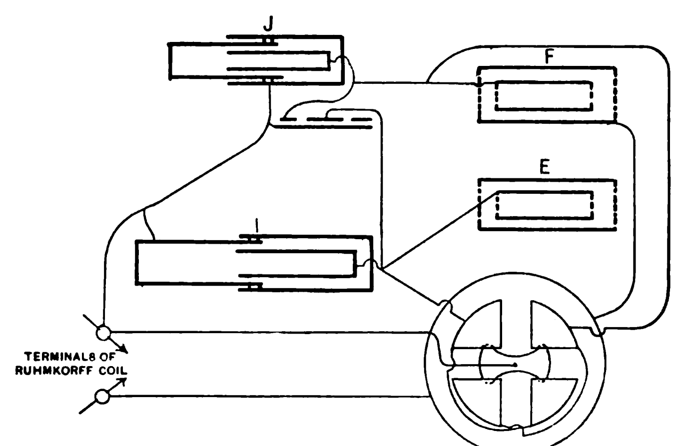

Fig.3.

Sesame.—K = 3.17.

A commercial sample of *raw linseed oil* gave K = 3.37.

Two samples of *castor oil* were tried; one newly purchased gave K = 4.82; the other had been in the laboratory a long time, and was dried over copper sulphate—

K = 4.84.

The result of my earlier experiments for castor oil was 4.78; the result obtained subsequently by Cohn and Arnos[4] is 4.48. Palaz gives 4.610.

1. "Phil. Trans.," 1881, part ii.
2. "Phil. Trans.," 1878, part i.
3. *La Lumière Electrique*, vol. 21, 1886, p. 97.
4. "Wiedemann's Annalen," vol. 28, p. 474.

Ether.—This substance as purchased, reputed chemically pure, does not insulate sufficiently well for experiment. I placed a sample purchased from Hopkin and Williams as pure, over quicklime, and then tested it. At first it insulated fairly well, and gave K = 4.75. In the course of a very few minutes K = 4.93, the insulation having declined so that observation was doubtful. After the lapse of a few minutes more observations became impossible. Professor Quincke in his first paper gives 4.623 and 4.660, and 4,394 in his second paper.

Bi-sulphide of Carbon.—The sample was purchased from Hopkin and Williams, and tested as it was received—

K = 2.67.

Professor Quincke finds 2.669 and 2.743 in his first paper, and 2.623 in his second. Palaz gives 2.609.

Amylene.—Purchased from Burgoyne and Company—

K = 2.05.

The refractive (μ) index for line D is 1.3800,

$\mu^2 = 1.9044$.

Of the benzol series four were tested: *benzol, toluol, xylol,* obtained from Hopkin and Williams, *cymol* from Burgoyne and Company.

In the following table the first column gives my own results, the second those of Palaz, the third my own determinations of the refractive index for line D at a temperature of 17.5° C., and the fourth the square of the refractive index:—

			μ	μ^2.
Benzol......	2.38	2.338	1.5038	2.2614
Toluol......	2.42	2.365	1.4990	2.2470
Xylol........	2.39	——	1.4913	2.2238
Cymol	2.25	——	1.4918	2.2254

For benzol Silow found 2.25, and Quincke finds 2.374.

The method employed by Palaz is very similar to that employed by myself in these experiments; but, so far as I can ascertain from his paper, he fails to take account of the induction between the case of his fluid condenser and his connecting wire; he also supports the inner coating of his fluid condenser on ebonite; and, so far as I can discover, fails to take account of the fact that this also would have the effect of diminishing to a small extent the apparent specific inductive capacity of the fluid. Possibly this may explain why his results are in all cases lower than mine. Determinations have also been made by Negreano ("Comptes Rendus," vol. 104, 1887, 423) by a method the same as that employed by myself.

Three substances have been tried with the guard-ring condenser—double extra condensed flint glass, paraffine wax, and rock salt. The first two were not determined with any very great care, as they were only intended to test the convenience of the method. For double extra dense flint glass a value 9.5 was found; the value I found by my old method was 9.896. For paraffine wax 2.31 was obtained—my previous value being 2.29. In the case of rock salt the sample was very rough, and too small; the result was a specific inductive capacity of about 18, a higher value than has yet been observed for any substance. It must, however, be received with great reserve, as the sample was very unfavorable, and I am not quite sure that conduction in the sample had not something to do with the result. In the experiments with the guard-ring condenser the disturbing effect of the connecting wire was not eliminated. My thanks are due to my pupil, Mr. Wordingham, for his valued help in carrying out the experiments.

ABSTRACTS AND EXTRACTS.

THE RADIAL DISTRIBUTION OF VARIABLE CURRENTS IN THICK WIRES.

THE question of the radial or sectional distribution of variable—and more especially of alternating—currents in conductors of large size is one upon which it will generally be confessed that very little light has dawned as yet upon the average electrician. It is usually, and vaguely, understood that—apart altogether from impedance—there exists a phenomenon by reason of which a given conductor when traversed by an alternating current of given mean square value presents a higher resistance, or causes a greater dissipation of energy, than when traversed by a continuous current of corresponding strength. It is, as a rule, still more vaguely held that this effect is due to a kind of tangential tendency, by reason of which the current density is greater in the exterior than in the interior layers of the conducting wire. The fundamental treatment of the subject is, of course, dealt with by Clerk-Maxwell (*cela va sans dire*); the question has also been experimentally as well as mathematically investigated by Lord Rayleigh (see *The Electrician*, vol. xviii., p. 170, *et seq.*). But hitherto no very tangible conception of the nature of this phenomenon has been placed within the reach of the non-mathematical reader.

We are indebted to a paper read before the Austrian Academy by Professor Stefan for a simple and intelligible exposition of the kind of action which takes place. Professor Stefan conveys his explanation by the aid of analogy. Imagine, he says (in effect), a cylinder or cylindrical wire heated throughout to a uniform temperature; let it suddenly be brought into a chamber where the temperature is higher. What will take place? Obviously the outer layers of the cylinder will first rise in temperature and gradually convey heat to the successive interior layers.

Precisely the same order of phenomena occurs if an E. M. F. is suddenly set up between the two ends of the wire or cylinder. The current during the so-called variable state passes first through the outer layers alone, and gradually (using this word in a relative sense) penetrates the inner layers. When the external E. M. F. is suddenly removed, and during the gradual cessation of current due to self-induction of the conductor, the action resembles, on the contrary, the cooling of a uniformly heated wire on passing into a colder medium—that is to say, the current ceases first, or rather *most quickly*, in the outer layers. Now, imagine that the wire is rapidly transferred to and fro between a hotter and a colder medium. It is quite easy to see not only that waves of heat will pass radially to and fro, but moreover that its condition at any moment depends very largely upon the *rapidity* of the rate of transference. When the rate of motion is sufficiently slow, the waves of heat passing any given point in the radius of the wire follow exactly with the periodic changes of position. The *amplitudes* of these variations have values which decrease from the surface inwards. When the rate of change is increased the amplitudes of the waves get shorter and shorter, and at an infinite velocity the wire would acquire an equable temperature throughout.

The electrical analogue is obvious from what has been already said, the rate of transfer corresponding to the inverse of the periodic time of an alternating current, the heat *conducting* power of the material corresponds to the electric *resistance*. But there is also the inductance of the wire, which plays a part opposed to that of the electric resistance, and which scarcely seems to have any distinct analogy in the heat system.

Professor Stefan gives some numerical illustrations which are valuable to fixed ideas, though many more will be found in the paper of Lord Rayleigh already referred to. With an *iron* wire of 4mm. diameter, and a periodic time of one 250th sec., the amplitude of the waves of current density is about twenty-five times as great upon the surface as at the axis of the wire. For double the number of vibrations per second the external amplitude becomes only six times as great. The difference of the phases is one-third the duration of the vibration in the first case and one-half in the second. The latter statement implies that the external current is at a given moment actually in the reverse direction to the internal current. For non-magnetic wires the difference is not nearly so marked, and it decreases also as the specific resistance increases. For a copper wire of 4mm. diameter with periodic time of one 500th sec. the difference between the current density at the surface and in the centre is only 14 per cent. If, however, the copper wire be increased to 20mm. diameter then we should get the same difference as in the particular iron wire above quoted.

It is obvious that the result of this non-homogenous distribution of the current is to increase the rate of dissipation of energy, which is, of course, proportionate in each transverse section to the square of the current in that section. In the case of the iron wire referred to above, augmentation of resistance is 48 per cent. at the lower rate of alternation and 100 per cent. at the higher. The resultant effect upon the self-induction is, however, to diminish the value of the coefficient. From this follows the apparent paradox that although the effective resistance is increased by the non-homogenous distribution of current, yet, under the same E. M. F., the current may for the same reason be greater. The effect in decreasing the resultant self-induction coefficient is more marked as the periodic time is lessened, until at length the decrease of impedance from this cause may have a most important influence in increasing the current.—*The Electrician* (London).

PRESENT POSITION AND PROSPECTS OF THE ELECTRIC LIGHTING INDUSTRY.

BY PROFESSOR EWING.

IN October last, Professor Ewing gave the first of a course of ten popular lectures on electric lighting in the engineering class room of University College, Dundee, the subject of the introductory lecture being "The Present Position and Prospects of the Electric Lighting Industry." After some preliminary remarks the lecturer went on to speak of the progress in electric lighting during the last five years, under the several heads of production of electricity, storage, distribution, and lamps. The apparatus was now vastly more efficient and very much cheaper. Doctor Fleming had lately shown that the first cost of a large dynamo was then about £2 per lamp; now it was only 7s. Lamps were now more durable. Storage batteries are trustworthy and permanent. By transformers it had become possible to convey

electric energy in the form of a current of small quantity at great pressure, thereby requiring only small conductors, and then converting that into currents of large quantity and low pressure, suitable for ordinary domestic use. By this means the problem of economically distributing electricity for incandescent lighting from a central station was in a fair way to be solved, and in the last year Mr. Westinghouse had put up 27 such stations. The electric meter of Professor Forbes, made public only last September, would serve to show how much electricity each householder was consuming, just as a gas meter did for gas. Apart from the question of general distribution from central stations, the electric light was now an assured success as the illuminant of large open spaces, of ships, of exhibitions, of theatres, of the country mansions of the rich, and of mills and factories. The question that determined the use of the electric light was almost wholly a question of cost. Was it or was it not cheaper than gas? To that question it was now possible to give a definite answer. Supposing, as was often the case in Dundee mills, the power required could be taken from the mill engine, then whenever night work was to be done, electric lighting by incandescent lamp was unquestionably cheaper than gas. If there was only day work—that is, if light was required only for a few hours in the early morning and the late afternoon of the winter months—then gas and electricity ran almost neck and neck as regards cost; but if light was wanted for anything like a thousand hours in the year, then electricity was distinctly cheaper, even allowing in the most liberal way for interest and depreciation on the permanent plant, as well as for the cost of lamp renewals, coal, oil, etc. More than two years ago he pointed this out in a lecture in Dundee as the result of a calculation, and shortly after he had the opportunity of making practical proof in mills in the Dundee district, where he had been consulted professionally regarding the electric light. In one of these factories the calender was lighted by electricity, and was used occasionally for night work. After two years' use the manager had given him figures for the actual cost. For 1,200 hours' work during one year the whole cost of lighting by electricity, including interest and depreciation, was under £50. The same area had formerly been lighted by gas, and the gas bill for the same number of hours' work had been £82. If the plant had been of the most modern kind, the difference would have been still greater in favor of electricity. In another case, in the underground warehouse of a Dundee mill, where they had formerly made shift to work with the dimmest light for fear of fire, the electric light had been introduced under his supervision, and the results had been very interesting. He recommended that, as a brilliant light was not wanted, the lamps should be worked, for the sake of economy, at a low degree of incandescence. This had been done, and some of the lamps, burning every working day for ten hours, had lasted for more than 7,000 hours. Their average life had been 5,500 hours. In conclusion, the lecturer said there were many signs that the electric light industry, after a long time of great depression—during which, however, the engineers had not been idle—was about to enter on a period of rapid growth.—*The Electrician* (London).

DR. BALFOUR STEWART, F. R. S.

In the genial Manchester Professor the scientific world has lost not only an excellent teacher of physics but one of its ablest and most original investigators. He was trained according to the best methods of the last generation of experimentalists, in which scrupulous accuracy was constantly associated with genuine scientific honesty. Men such as he was are never numerous; but they are the true leaders of scientific progress :—*directly*, by their own contributions ; *indirectly*, though (with rare exceptions) even more substantially, by handing on to their students the choicest traditions of a past age, mellowed by time and enriched from the experience of the present. The name of Stewart will long be remembered for more than one striking addition to our knowledge, but his patient and reverent spirit will continue to impress for good the minds and the work of all who have come under its influence.

He was born in Edinburgh on November 1, 1828, so that he had entered his sixtieth year. He studied for a short time in each of the Universities of St. Andrews and Edinburgh, and began practical life in a mercantile office. In the course of a business voyage to Australia his particular taste for physical science developed itself, and his first published papers :—"On the adaptation of the eye to different rays," and "On the influence of gravity on the physical condition of the moon's surface," appeared in the *Transactions of the Physical Society of Victoria* in 1855. On his return he gave up business for science, and resumed study under Kelland and Forbes, to the latter of whom he soon became assistant. In this capacity he had much to do with the teaching of natural philosophy on occasions when Forbes was temporarily disabled by his broken health. During this period, in 1858, Stewart was led to his well-known extension of Prévost's *Law of Exchanges*, a most remarkable and important contribution to the theory of radiation. He seems to have been the first even to suggest, from a scientific standpoint, that radiation is not a mere surface phenomenon. With the aid of Forbes's apparatus, then perhaps unequaled in any British University, he fully demonstrated the truth of the conclusions to which he had been led by theory ; and the award of the Rumford medal by the Royal Society some years later, showed that his work had been estimated at its true value, at least in the scientific world. In fact his proof of the necessary equality between the radiating and the absorbing powers of every substance (when divested of some of the unnecessary excrescences which often mask the real merit of the earlier writings of a young author) remains to this day the simplest and therefore the most convincing that has yet been given.

Radiant heat was, justly, one of Professor Forbes's pet subjects, and was therefore brought very prominently before his assistant. Another was meteorology, and to this Stewart devoted himself with such enthusiasm and success that in 1859 he was appointed director of the Kew Observatory. How, for eleven years, he there maintained and improved upon the memorable labors of Ronalds and Welsh needs only to be mentioned here—it will be found in detail in the *Reports of the British Association*. Every species of inquiry which had to be carried out at Kew, whether it consisted in the testing of thermometers, sextants, pendulums, aneroids, or dipping-needles, the recording of atmospheric electricity, the determination of the freezing point of mercury or the melting point of paraffine, or the careful study of the peculiarities of the air-thermometer, received the benefit of his valuable suggestions and was carried out with his scrupulous accuracy.

About twenty years ago Stewart met with a frightful railway accident, from the effects of which he did not fully recover. He was permanently lamed and sustained severe injury to his constitution. From the vigorous activity of the prime of life he passed, in a few months, to grey-headed old age. But his characteristic patience was unruffled and his intellect unimpaired.

His career as Professor of physics in the Owens College has been, since his appointment in 1870, brilliantly successful. It has led to the production of an excellent treatise on *Practical Physics*, in which every necessary detail is given with masterly precision, and which contains (what is even more valuable, and could only have been secured to the world by such a publication) the matured convictions of a thorough experimenter as to the choice of methods for the attack of each special problem.

His *Elementary Physics* and his *Conservation of Energy* are popular works on physics rather than scientific treatises, but his *Treatise on Heat* is one of the best in any language, a thoroughly scientific work, specially characteristic of the bent of mind of its author.

Stewart published, in addition to his *Kew Reports*, a very large number of scientific memoirs and short papers. Many of these (notably the article in the *Encyc. Brit.*, 9th ed.) deal with terrestrial magnetism, in itself as well as in its relations to the Aurora and to solar disturbances. A valuable series of papers, partly his own, partly written in conjunction with De la Rue and Lœwy, deals with solar physics. His paper on the *Occurrence of Flint Implements in the Drift* (*Phil., Mag.* 1862, i.) seems to have been ignored by the "advanced" geologists, one of whose pet theories it tends to dethrone ; and to have been noticed only by physicists, especially Sir W. Thomson, whose beautiful experiments have done so much to confirm it. His paper on *Internal Radiation in Uniaxial Crystals*, to which Stokes alone seems to have paid any attention, shows what Stewart might have done in mathematical physics had he further developed the genuine mathematical power which he exhibited while a student of Kelland's.

I made Stewart's acquaintance in 1861, when he was the first-appointed additional examiner in mathematics in the University of Edinburgh, a post which he filled with great distinction for five years. A number of tentative investigations ultimately based upon our ideas as to possible viscosity of the luminiferous medium, effect of gravitation-potential on the physical properties of matter, etc., led to the publication of papers on *Rotation of a disc in vacuo*, *Observations with a rigid spectroscope*, *Solar spots and planetary configurations*, etc. These, as well as our joint work called *The Unseen Universe*, have been very differently estimated by different classes of critics. Of course I cannot myself discuss their value. There is, however, one of these speculations so closely connected with Stewart's radiation work as to require particular mention, especially as it seems not yet to have received proper consideration, viz. *Equilibrium of Temperature in an enclosure containing matter in visible motion.* (*Nature*, 1871 ; iv. 331.) The speculations are all of a somewhat transcendental character, and therefore very hard to reduce to forms in which they can be experimentally tested ; but there can be no doubt that Stewart had the full conviction that there is in them all an underlying reality, the discovery of whose exact nature would at once largely increase our knowledge.

Of the man himself I cannot trust myself to speak. What I *could* say will easily be divined by those who knew him intimately, and to those who did not know him I am unwilling to speak in terms which, to them, would certainly appear exaggerated.—P. G. TAIT, in *Nature*, Dec. 29, 1887.

MR. EDISON ON THE PATENT LAW.

MR. EDISON said recently, when questioned as to the patent rights in the phonograph: "I always thought that my original patent of twelve years ago covered the essential features of the phonograph so completely as to give me a monopoly of the perfected instrument whenever I, or any one else, should find time to finish it. Within the last few years, however, I have become extremely skeptical as to the value of any patent, and so long as our patent law remains in its present iniquitous shape, I shall try to do without patents. The present law is a constant temptation to rascals, and virtually offers a premium upon rascality. Under it the infringer of a patent is not interfered with until the real owner can show that he has the monopoly of the device in question. This process may take years, during which the infringer, who has money and audacity enough to seize another man's invention, can go on and perhaps wear the rightful owner's life out by litigation and annoyance. I have had so much of this sort of thing within the last five years, that I have almost made up my mind never to take out another patent until the law is changed. The burden of proof is now put entirely upon the man who holds the patent instead of upon the man who wishes to infringe it, whereas it ought to be all the other way.

"There is scarcely an invention of importance made within the last generation which has not been disputed upon frivolous grounds, and the inventor put to all sorts of annoyance. In my own case. I am sure that no matter what I may patent, some one will come up as soon as the patent is seen to have any value, and show, by dozens of witnesses if necessary, that he is the rightful owner of the invention. If I patent to-morrow a process for making good flour at a cost of two cents a barrel, the publication of my patent would bring out about ten men who could prove that they did that sort of thing years ago, and that I had no right to a patent. In the case of my dynamos, I have patents by the score, and yet when a great firm of machinists want to go into the business of making dynamos, they coolly appropriate one hundred of my inventions, and laugh at my claims as patentee. To litigate the matter to the end, if there was any end in sight, would cost hundreds of thousands of dollars, and put me in hot water for years to come. I am an inventor and not a lawyer, and I hate litigation. If patents are going to give me nothing but lawsuits, I don't want any more of them.

"In the case of the phonograph, these Washington people have had the decency to come here to Orange and ask for my permission to manufacture and sell their devices; they wanted a license, which I refused to give them. Having no license, they go to work at once and proclaim the worthlessness of all patents upon the phonograph except their own; they have got some patents for twisting a screw to the right instead of the left, etc. I really can't say what our first steps will be, and I leave all those matters to the lawyers, who enjoy that sort of business. Certainly if the phonograph turns out to be the great commercial success that I expect for it, there will be a dozen infringements upon the market within the next six months, and the lawyers will have their hands full.

"I am so thoroughly convinced of the uselessness of patents, that one of my objects in building my present laboratory is to search for trade secrets that require no patents, and may be sources of profit until some one else discovers them. There are scores and scores of such secret processes, which are enormously profitable and which are not claimed right and left, just because they are secrets. Some are used in this country, but most of them, chiefly chemical, are held in Europe. Methods of dyeing, of working certain fabrics, etc., pay millions every year to those who know the secret processes employed. I have already found one chemical device which promises to pay me handsomely, and the patent-office will never hear anything about it. To apply for a patent would simply invite a lot of rogues to share with me, or, what is more likely, to take all the profits. I am rather curious to see what is to be done when the phonograph comes out. The patent has only five years to run, and evidently, if men with millions behind them jump into the manufacture upon a large scale, the patent may run out before my claim to the fundamental device is allowed."—*N. Y. Evening Post.*

COPPER PRODUCTION IN 1887.

THE *Engineering and Mining Journal* gives an elaborate review of copper production and trade in 1887, and places the production of this country at 177,200,000 pounds, against 156,735,381 pounds in 1886, and 165,875,766 pounds in 1885. It estimates the consumption of copper in 1887 at 140,500,000 pounds, exports at 45,000,000 pounds, and the stock on hand Jan. 1, 1888, at 27,000,000 pounds, against 30,000,000 pounds Jan. 1, 1887. It estimates the output of the Lake Superior mines in 1888 at not exceeding 85,000,000 pounds, and the Montana output at not exceeding 90,000,000 pounds, and the output of all mines in this country at 200,000,000 to 210,000,000 pounds. It puts the average price of lake copper in New York at 11¼c., the range being from 10c. in May and June to 17c. in December. Here is its estimate of the copper production of the United States in 1887, from complete and partial returns;

	Pounds.
LAKE MINES.	
Calumet & Hecla	45,600,000
Quincy	5,502,000
Osceola	3,565,000
Franklin	3,924,000
Allouez	885,000
Atlantic	3,550,000
Central	2,000,000
Copper Falls	560,000
Phœnix	11,000
Huron	1,471,000
Ridge	85,000
Cliff	2,300
National	25,200
Tamarack	7,390,000
Kearsarge	22,000
Tributers	67,500
Total, 1887	74,660,000
Colorado	2,000,000
Other states and territories	2,400,000
Lead desilverizers	1,240,000
From foreign ores	5,300,000
MONTANA MINES.	
Anaconda	57,000,000
Parrott	10,000,000
Boston & Montana	1,500,000
Clark's Colusa	7,100,000
Butte reduction works	1,565,000
Williams	1,495,000
Other mines	240,000
Total, 1887	78,900,000
ARIZONA MINES.	
Copper Queen	5,945,550
Old Dominion	1,444,770
Arizona Copper Co	5,714,000
Detroit Copper Co	4,404,321
United Verde	272,124
Other mines	219,235
Total	18,000,000
Grand total, all mines	182,500,000

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

(Continued from page 17.)

IT was noticed in the last paper that solutions of the perchloride and persulphate of iron yielded no deposit of metallic iron upon the cathode. It was next determined to ascertain the behavior of a solution of the pernitrate of iron, employing the liquid at various degrees of concentration, with a current from two to five small Daniell cells progressively, the cells being arranged in series. The anode, as in the former cases, consisted of a plate of wrought iron, and the cathode a strip of sheet copper.

Pernitrate of Iron.—A concentrated solution of this salt was prepared by digesting fragments of iron in a solution composed of equal parts of nitric acid and water. On the following day the solution was ready for use. To form the electrolyte, for the first trial, five fluid drachms of the pernitrate solution were added to five ounces of water. Two Daniells were used, and the electrodes then immersed, their surfaces being about equal. During the first few seconds no apparent deposit took place, so the cathode was moved about quietly, when a slight film of iron began to form. The plate was then allowed to rest for about two minutes, at the end of which time it became coated with a thick black deposit, interspersed with bubbles of hydrogen, which rested firmly on the plate. Surrounding these gas bubbles were minute glistening particles of metallic iron, which had evidently been reduced by the hydrogen. The plate was now carefully rinsed so as not to disturb the coating, and was then held over the flame of a small lamp, at a moderate distance from the flame, until the black deposit became dry on both sides of the plate. During the process of drying, the deposit suddenly broke up into minute particles, leaving the copper surface exposed. The particles were then brushed off and collected upon a piece of white paper. Upon holding a magnet below the surface of the paper the granules were powerfully attracted, proving that they consisted of metallic iron in a very finely divided state. A second plate was then immersed in the bath and allowed to rest for about five minutes, by which time it became very thickly coated with the same black deposit, which was afterwards washed, dried and collected as before. An attempt was next made to induce the metal to deposit in a reguline form, by diluting the solution considerably. In this case, as before, a slight reguline film appeared upon the copper plate when it was kept in motion, but so soon as it was allowed to remain stationary the black deposit again formed, and after a few minutes immersion it stripped off the plate (doubtless dislodged by the hydrogen bubbles) and accumulated at the bottom of the vessel. The black deposit was afterwards collected, washed and dried as before, and the resulting black dust tested with the magnet, by which it was powerfully attracted. A still weaker solution was next tried, with a precisely similar result, and the plate was allowed to remain in the bath for about 10 min-

utes, during which time the black deposit from the cathode accumulated on the surface of the liquid, nearly covering its entire surface in fact, the fine particles of iron being held in suspension by the hydrogen bubbles, with which it was intimately mixed. The solution eventually became nearly colorless, while the anode was but slightly acted upon. It should be mentioned that the evolution of gas was much more copious with the weaker than than with the stronger solutions, while in some cases bubbles of gas nearly as large as a pea rested upon the plate for at least a minute before bursting. In reflecting upon the character of the dried deposit of iron above described, it appears to me to resemble the pharmaceutical product known as *Quevenne's Iron*, which is prepared by passing a stream of dry hydrogen gas through red hot sesquioxide of iron contained in a gun barrel, the object of which is to reduce the iron in a very finely divided state, by which it may readily become dissolved by the juices of the stomach, thus forming a useful and effective chalybeate. The formation of *impalpable metallic iron* in the way I have indicated would be a far cheaper and less troublesome method than either of the processes adopted for preparing Quevenne's iron; indeed, I am disposed to think that the iron could be produced in a more finely divided state electrolytically than by the pharmaceutical methods.

Citrate of Iron.—A solution of this salt was prepared by dissolving recently precipitated carbonate of iron in a moderately strong and hot solution of citric acid, the carbonate being added a little at a time until evidence of neutralization occurred, which became known by the liquid remaining turbid after the last addition of the iron salt was made; an excess of citric acid was then given, not only to clear the liquid, but to assist the solution of the anode. The solution was used cold, and two small Daniells at first employed. A clean strip of sheet copper received a white and bright deposit of iron soon after the immersion, but as the deposit was scarcely rapid enough, a third cell was connected, when deposition took place freely upon a newly prepared plate. After two hours' immersion a good bright deposit was obtained, which thickened at the lower edges in the form of minute nodules. The film, which was of a silvery whiteness, was of a thoroughly reguline character, excessively hard, and readily attracted by the magnet. On examining the anode, it appeared to have been very freely and uniformly acted upon. Five cells were next tried, when the deposit became more rapid, but still maintained its bright and silvery lustre, being even whiter than the best Damascus steel.

Cyanides of Iron.—The various cyanide salts of iron were tried, but not one of them yielded a reguline deposit of the metal. The only solution of this class which gave a tolerably successful result was that of the sulphocyanide of iron, from which a darkish film, of an iron grey color, was obtained upon a copper plate by keeping it continually in motion; no deposit appeared to take place upon a stationary electrode. While deposition was going on under these conditions a dirty white deposit formed upon the anode which was insoluble in the liquid.

Sulphate of Iron and Chloride of Ammonium.—A solution of the mixed salts has been applied by Meidinger and others for coating copper plate with iron. For this purpose the following proportions give very satisfactory results:—Sulphate of iron, 2oz., dissolved in water 1 pint; sal-ammoniac, 1¼ oz., dissolved in water 1 pint. These solutions were mixed, and a few drops of acetic acid added. With the current from two Daniell cells, and electrode surfaces about equal, a reguline deposit of iron was obtained upon a copper plate from a bath prepared as above immediately after immersion. There was but moderate evolution of gas, and the film was exceedingly uniform and of good color, though neither so bright nor so purely white as the deposits from the simple sulphate or citrate salts. After half an hour's immersion, the coating, though otherwise faultless, assumed a dull appearance; there was no blackening at the edges of the plate, however, nor any other irregularity of the surface of an objectionable nature. There was a slight deposit of peroxide, however, which would doubtless continue to form, but since this readily finds its way to the bottom of the vessel it does not necessarily interfere with the film, provided the liquid be kept in a deep vessel and the deposited oxide allowed to remain undisturbed when immersing or withdrawing the coated plates. On examining the anode (a plate of wrought iron) it appeared to have been pretty uniformly acted upon, and exhibited the characteristic crystalline appearance of iron which has been subjected to the solvent action of weak acid solutions. The deposit upon the cathode, after one hour's immersion, had become somewhat more dull, but otherwise the coating was perfectly uniform and of good quality.

Protacetate of Iron.—A solution of this salt was prepared by dissolving freshly precipitated carbonate of iron in dilute acetic acid, of which it is a ready solvent. The carbonate of iron was added in moderate quantities at a time, until the acid became neutralized, when a small addition of free acetic acid was made, and the bath, after filtering, was ready for use. The current from three small Daniells was employed, and the surface of the positive electrode was about three times that of the cathode. Under these conditions a good white deposit was promptly obtained, the film being of a perfectly reguline character. After a short immersion of the electrodes the anode was examined, and proved to have been freely acted upon. There was a slight disposition for the deposit to blacken in the centre of the negative plate, which was remedied by immersing a larger surface of anode. The deposition was now allowed to proceed undisturbed for about two hours, at the end of which time it was found that the solution had become considerably oxidized, there being a copious deposit of peroxide of iron at the bottom of the vessel; at the same time the deposit had lost its reguline character; and became black and pulverulent, while the anode was considerably eaten away.

Sesquiacetate of Iron.—A solution of this salt was prepared by dissolving freshly precipitated hydrated sesquioxide of iron in acetic acid, the solution being afterwards moderately diluted and filtered. There was practically no deposit obtained from this solution, even when brisk motion was given to the cathode.

Ammonio-Chloride of Iron.—A bath was prepared by adding to a solution of perchloride of iron another of chloride of ammonium, the combined liquids being of moderate strength. Five cells were used, and a large anode surface exposed. On immersing the negative plate (a strip of copper) it received a partial coating of a dark color, but while the plate was stationary in the liquid there was practically no deposit. When the plate was briskly moved about a slight film appeared all over the immersed surface, which was black at the lower corners; beyond this there was no deposit obtainable. The solution was next diluted with a considerable proportion of water, when the plate became coated with a black film of iron in a finely divided state, similar to that obtained from the pernitrate, but much more slowly formed. The results, however, had no practical significance.

Oxalate of Iron.—A solution was formed by dissolving freshly precipitated carbonate of iron in a strong solution of oxalic acid. The iron salt dissolved very freely, with evolution of carbonic acid, leaving a clear solution, which was next diluted with water. With two Daniells no deposit took place upon a copper cathode while it remained stationary in the liquid; when this electrode was briskly moved about, however, a white film of iron was obtained, which gradually increased in thickness so long as the agitation was kept up. During the electrolysis the solution became decomposed, and a deposit of peroxide settled at the bottom of the vessel. Five cells were also tried, but there was no deposit of reguline metal unless the cathode was kept in brisk motion.—*The Electrician* (London).

CORRESPONDENCE.

NEW YORK AND VICINITY.

An Effort to Regulate Anchorage in the Vicinity of Cable Crossings in New York Harbor.—Mr. Michael Breslin.—Postal Telegraphy.—The Substitution of Electricity for the Gallows.—The American Institute of Electrical Engineers; Dr. Duncan, of Johns Hopkins University, to Read a Paper on Alternate Current Motors February 14.—The Board of Electrical Control and the Subways.—A Citizen of New Jersey tried for Cutting Down a Telegraph Pole, found "Not Guilty."—Magnetism and Watches.—Opening of the Electric Club House.

ALL electrical companies having cables across the North river should be interested in knowing that Captain John Vosburgh, of the Schuyler Towing Co., and other gentlemen have gone to Washington to secure legislation empowering the Lighthouse Board, or other proper department, to regulate the anchorage of vessels in the North river. In the absence of any regulations, the various skippers anchor to suit their own convenience, without regard to their annoyance of other people. If a reform is effected, it will no doubt prevent much future damage to cables.

Mr. Michael Breslin, who has been chief batteryman for the Gold and Stock Telegraph Co. since its organization twenty years ago, has recently been elected treasurer of District 49, K. of L. Mr. Breslin has also held for several years the office of treasurer of the Gold and Stock Life Insurance Association. He is a man of sterling integrity, and an earnest though conservative advocate of labor organization.

The attention of the New York *Sun*, which claims that there is no authority under the constitution for the government engaging in telegraphy, should be directed to the recent establishment of a line between Titusville, Fla., and Jupiter Inlet, over which all vessels passing the lighthouse at the latter point are to be reported. Commercial messages will also be transmitted at the rate of 10 cents for 10 words. Offices will also be equipped at the hotels along the line, provided the proprietors furnish operators at their own expense. The line is in charge of Lieut. B. M. Pursell.

The report of the state commission in favor of substituting electricity for the rope in the execution of the death penalty is rather a doubtful compliment to electricity, and it is questionable whether any lighting company will feel inclined to furnish a current for that purpose. A French mechanic has written Governor Hill from Paris that death by electricity is painful, and submits his device for instantly breaking the spinal column as an improvement over all other methods. A hundred cases per day can be

readily disposed of by this machine, which the inventor describes as "beautiful."

The next meeting of the American Institute of Electrical Engineers will be held on February 14th, when a paper will be read by Dr. Louis Duncan, of Johns Hopkins University, on Alternate Current Motors. This subject has been touched upon in several discussions before the Institute, but this is the first occasion when it has been the leading topic. The interest that has been shown in it leads to the belief that it will be a very important gathering.

The Board of Electrical Control met on Friday, the principal business appearing to be the adoption of such legislation as would force the various electrical companies to remove their poles in streets where conduits are ready for occupancy. It is generally believed that the accommodations in the man-holes are by no means equal to the conduit capacity, and that considerable difficulty will be experienced in making connections after a limited number of cables have been drawn in. This would lead to a rush for first choice but for the fact that some of the companies believe that by waiting until the man-holes are full they will have a legitimate excuse for not going underground.

Commissioner Gibbens does not confine his tilts with Mayor Hewitt to subway matters, but has sent a letter to the papers severely criticising his honor's advocacy of the "single tax" doctrine. The mayor's reply, through the medium of an interviewer, was that Mr. Gibbens was a young man, and had much to learn.

In July last George Addy, a retired blacksmith, of Paterson, N. J., after repeated but ineffectual remonstrances against the planting of a telephone pole in front of his premises, cut it down and severed the wires, among them being one of the fire alarm circuits. Complaints were made against him by the city authorities, and two indictments were found against him by the grand jury. The case came up for trial before Judge Nixon and a jury on January 16th, and resulted in a verdict of not guilty. The remaining indictment is for destroying the property of the telephone company, and is yet to be tried.

There appears to be a conspiracy on foot to force the watch-carrying public either to sell, give away or exchange their cherished timepieces and invest in something which is non-magnetic. In fact magnetism is assuming the same role in watch-repairing circles that has long been maintained by malaria in medical practice. A newspaper paragraph gives as a definition for malaria: "A huge blanket let down over the surface of the earth, under which physicians hide their ignorance." The old fiction of a "broken main-spring" is now discarded, and when your watch is returned to the man who is supposed to have cleaned it with the statement that it loses five minutes a day and that it don't mind its helm, he looks wise and says it has been magnetized. Then for a fee which will buy a couple of Waterburys, he will send it round to a man who has a Maxim machine, which will remove the stagnant juice, and the watch owner will be happier, yet poorer. Waltham has come to the front with a non-magnetic watch, and Benedict's south window is well filled with them. A C & C motor stands in the centre, with a dozen or more horse-shoe magnets of various sizes with watches laid upon the poles and ticking vigorously. All of this is for the purpose of proving that magnetism has no effect on watches of this character. There is a continually increasing army of small boys who will gladly absorb all discarded watches if the opportunity is offered to secure them at nominal prices.

The formal opening of the new house of the Electric Club is to take place Tuesday evening, January 31. The occasion promises to be most enjoyable and interesting. Professor Rowland, of Johns Hopkins University, will make an address. It is needless to say that a large and jovial assemblage will be found at 17 East 22d street, next Tuesday evening.

NEW YORK, Jan. 24, 1888.

PHILADELPHIA.

The Philadelphia Bell Telephone Co. Obtains an Underground Franchise.—Ordinances Granting Privileges to the Keystone and the Edison Electric Light Companies Favorably Reported. —Bids for Public Electric Lighting.

THE Bell telephone underground ordinance passed select councils by a nearly unanimous vote, a few days ago. The obstructionists to the bill tried very hard to defeat it by loading it down with various amendments, but it finally went through with flying colors.

While the Bell people have not been making quite as much noise as some of the other corporations seeking underground privileges, they, nevertheless, seem to have "got there" all the same, way ahead of the rest of them. It is probable that superintendent Gill and Mr. George Snyder brought their eloquence and persuasive powers to bear to accomplish this gratifying result. An ordinary councilman could not hope to withstand their combined assault.

Before the passage of the ordinance, Mr. Bardsley said, if it was the intention to burden the bill with amendments it would fail. If they wanted the wires underground they must legislate in good faith.

Another member said that it was not a question of burying the wires. The Bell Telephone Co. wanted to extend their privileges and increase their business. When a monopoly with its stock far above par, asked to extend its privileges the city ought to be compensated. He offered an amendment, charging for the privileges a species of rental amounting to three per cent. of the company's gross receipts. The privileges to become null and void and the bond to be forfeited in case of default. (This member does not seem to be overburdened with modesty.)

Mr. Fow remarked that he thought commercial enterprises should be fostered, and made a strong point of the fact that the Supreme Court had decided that a municipality had no right to attach any condition to a grant. Mr. Scott said a special act authorized such conditions in grants to telegraph companies. Mr. Fow said the Bell was not a telegraph company. They had the privilege of running the wires all over the country. They did not want to extend their privileges, but to get their wires underground, out of the way of the public in general and the firemen in particular, and they ought not to be caught by the throat. (Sensible man.)

After further discussion, pro and con, Mr. Bardsley referred to the experience of councils with the steam-heat and power company as a case in which the courts had decided against councils' power to attach conditions to their grants, but said that soon after that decision some pipes exploded in New York, and the project of having such a corporation in this city exploded with them. He added that some of the companies were mere stock jobbing concerns, and contrasted with them the solid character of the Bell Telephone Co.

Both the Keystone and Edison Electric Light companies have been favored by a sub-committee of the electrical committee of councils. The Keystone ordinance, as submitted to the committee, provided for a district bounded by Sansom and Arch, and extending from river to river.

Mr. Rudderow, being the representative of the Keystone company, said if the privileges they asked were granted, that is from river to river, between Arch and Walnut, they would light the City Hall, in addition to the other city property they had promised to light, gratis. "We want," said he, "to get to the Schuylkill so that we can erect our plant."

Mr. Wagner wanted to know if they would light the city lamps at 35 cents each.

Mr. Rudderow replied that it would not pay them at that price unless they could get to the Schuylkill.

Mr. Graham urged a proviso binding the company to light all municipal buildings but the City Hall, free of cost. His proviso and amendment were both approved, and in that shape the Keystone bill was at last ordered to be reported favorably.

As the Penn company had already put down conduits, which the Edison will use in a number of streets, the names of such streets were stricken from the Edison ordinance, which was then ordered to be favorably reported with the same proviso that had been attached to the Keystone ordinance as to their obligation to light in return for their privileges all public buildings but the City Hall.

Director Wagner has refused to award contracts for electric lighting at the figures bid by the companies in the Electric Trust, and will send the bids to councils for their consideration. The following are the bids referred to :—

United States Electric Light Co.—North from north side of Market to south side of Poplar street, and east from the west side of Broad street to the Delaware river, 50 cents.

Brush Electric Light Co.—South side of Market to the north side of Spruce, from river to river, 47½ cents; south side of Spruce to the north side of Washington avenue, 50 cents; below and including south side of Washington avenue, 54 cents; west side of Schuylkill, 50 cents; north side of Market and west of Broad, to south side of Callowhill, 47½ cents.

Philadelphia Electric Light Co.—West from the east side of Broad street and north from the south side of Callowhill, 47½ cents; west from the south side of Callowhill, between Eighth and Broad, 49½ cents; north from the south side of Callowhill, between Eighth and Sixth, 52½ cents.

Keystone Light and Power Co.—Between Arch and Walnut streets, from river to river, 35 cents.

Northern Electric Light Co.—North of, including Poplar, and east of, including Thirteenth, 49 cents.

Germantown Electric Light Co.—All territory in Germantown, 55 cents.

Frankford Electric Light Co.—Twenty-third ward and front of Twenty-fifth ward, 55 cents.

Wissahickon Electric Light Co.—All territory in Manayunk, 55 cents.

The specifications required that the lights shall be electric arc lights of at least 2,000 c. p., and they must burn nightly from sunset to sunrise. Lights burning less than eight hours in any one night will not be paid for. No lights beyond the registered capacity of the dynamo shall be attached to the wire furnishing the city lights. The failure of the lights for two nights shall be sufficient cause for the annulment of the contract.

Director Wagner said his idea in having the whole subject referred to councils, was, because after considering the bid of the Keystone Electric Light Co., which offers to light the central part of the city at the rate of 35 cents per lamp, which would make a difference of nearly $100 a day as compared with the price asked by other bidders. My idea is to refer all the bids to councils, and in the meantime to ask these gentlemen to continue to light the lamps on the basis of the rates mentioned in the bids. Two of these bids are very peculiar. The specifications call for arc lights of 2,000 c. p. Two of the companies in the rural districts say that they cannot furnish lights of that power, and that no company in the city has done so.

The director said he did not think there was in the city a light of 2,000 c. p., as required by contract. Chief Walker explained that while the nominal power of the lights was 2,000 candles it was really only 915—a statement which was all the more interesting as the companies had said that the reason why lights could be supplied much more cheaply in small cities than in Philadelphia was because they were not required to be of only 1,200 c. p.

"The president of the Germantown company," the director stated, "said that his company furnished a 1,200 power light, and that that was as good as any light furnished in the city. It is the suggestion of the mayor that this whole matter be carried over for 90 days, until councils have had an opportunity to act on the matter. Our purpose is to ask the companies to go on lighting the lamps; if they refuse, we will go on lighting with gas. There is another matter to be considered. There is an ordinance which gives the Department of Public Works the right to erect poles for electric lighting in the central part of the city, but there is no inclination of the department in that direction. That would probably enable us to get the light at a lower figure, but I doubt whether the result would justify us in encumbering the streets with more poles."

A gentleman largely interested in electric lighting, in speaking of the comparison made in regard to the cheapness of illuminating inland towns throughout the state, as compared with the high price charged in Philadelphia, said:

"Any one at all familiar with the arc lighting business understands that such lighting cannot be furnished for less than 50 cents an arc light, as expenses now go."

"In considering this subject you must remember that the relations are different between the companies and the various cities. For instance, in the inland towns quoted by the councilmanic authority on electric lighting other conditions prevail.

"Here we light the streets every night all the time between twilight and sunlight. In the towns and cities in which such low rates are quoted in comparison with ours you will find that they do not attempt to light the streets on moonlight nights.

"Then besides there is a difference in the candle-power of the light furnished. The interior towns receive a light of a power of 1,200 candles; here patrons are given just twice as much. A most important factor, too, is the amount of capital invested. These old companies I speak of were the first in the field and had to spend a great deal of money. The territory was very extended and the business had yet to be sounded. For the men who originated this enterprise there was the greatest amount of risk and considerable loss.

"In the other towns spoken of less capital is needed and smaller plants are required. These with the other advantages I have mentioned, such as shorter time for lighting and a practical monopoly of the privileges of the town, make it easy for the companies having the town franchises to make money.

"The fact remains to be told that the pioneer companies in the electric lighting field in the large cities have never until now begun to pay the stockholders any return for the money which they originally invested. The Brush company, as you remember, lighted the streets in the central portion of the city for a whole year and all for nothing. I am quite positive, continued the gentleman, "that lower prices will rule as soon as the business justifies it."

There was a lively scene the other day in chief Walker's office over councilman Scott's motion with reference to the ordinance of the Brush and Maxim electric light companies. The sub-committee on the electrical department held a meeting to report upon the matter. Councilman Scott wants to repeal so much of the ordinances of these two companies as applies to privileges for the laying of underground wires. Mr Thomas Dolan, president of the Brush company, said Mr. Scott knew nothing whatever of the subject. President Walker hoped that Mr. Scott's ordinance would not pass, as after January, 1886, no overhead wires could be put up except for public lighting.

Mr. Dolan said that after five years of experiment the company had failed to find any system which would work for long distances, and referred to the fact that in Europe there was no underground system of wires.

He also alluded to several explosions that had occurred at the Brush company's building through experiments with underground wires, and asked the chief if there was not an explosion anly a day or so ago on Broad street, below Fairmount avenue, in the city's underground plant.

Chief Walker—Yes, that's so.

Mr. Dolan asked if there was not danger from gas wherever an arc light was formed, and the chief said there was, and also asserted that the bed of the city streets was saturated with gas.

The discussion ended with the sub-committee deciding to report negatively upon both ordinances.

President Dolan denied the report that the Brush had doubled its stock instead of declaring dividend. The Brush company had expended $400,000 and the Maxim $300,000 in experiments with underground wires.

In reference to the story that during last spring, when the Penn, the Edison and the Keystone companies were fighting for privileges in city councils, the Keystone company employed Pinkerton detectives to shadow the city councilmen, Mr. Rudderow says: "I deny that the employment of detectives had any reference to members of councils. We wanted to know what the Penn people were doing, as the information was of value to us. What the company did in employing detectives to investigate the Penn Electric Light Co., was nothing to be ashamed of. It was entirely a business measure and how anybody could imagine that it bore any relation to any councilman, I fail to understand. The detective work was our private business, and had nothing whatever to do with councils."

PHILADELPHIA, Jan. 15, 1888.

BOSTON.

Electricity Discussed at the Merchants' Club Dinner.—Another Trial of an Electric Car by the West En l Co.—Underground Telegraph and Telephone Wires.—Report of the Underground Wire Committee of the Board of Aldermen.—The Cambridge Electric Light Co.—Use of Electric Lamps under Water.—Electricity in Horse-Training.—The Western Union Company Sued for State Taxes.—Special Provisions by the Signal Service for Announcing the Approach of Snow Storms.—Annual Output of the American Bell Telephone Co.—Dinner given to Superintendents and Managers by the Officers of the New England Telephone Co.

PRESIDENT Richard Briggs was at the head of the table at Parker's, crowded around which sat seventy-five gentlemen, members and guests of the Merchants' Club, last evening. Among these guests were Professor C. R. Cross, of the Massachusetts Institute of Technology, Dr. C. J. Blake, Professor W. W. Jacques, President H. M. Whitney of the West End Street Railway Co., Colonel G. H. Benton, Jr., Rev. Stopford Brooke, C. A. Coffin, and Mr. E. H. Johnson, President of the Edison Electric Light Co.

After dinner the president introduced Professor Cross, who said that all we know of electricity was the phenomena in which it played a part and the effect which it produced. Electricity is apparently not ordinary matter; it does not have the property of inertia, which is the fundamental characteristic of matter. Neither is it a form of energy. It is an existent something which is apparently not ordinary matter, and it is certainly not energy. The mere fact that we cannot define it except by negation does not prevent our measuring it, perhaps more accurately than we can measure anything else. We can also separate it into parts. The possibilities of transmitting speech electrically depends upon the production, by means of the sound waves, of electrical changes, variations which shall be wavelike in their nature.

Professor Johnson said that the telephone had been in existence ten years. Last year it had been used to transmit 600,000,000 messages. On an average every man, woman and child spoke into the telephone each once a month. He thought the most important use of electricity was the transmission of sound. The invention in the telephone was a conception by which electric waves could be carried with very great rapidity and perfect accuracy to very great distances and there reconverted into sound waves.

Mr. Whitney, who was introduced as a merchant, said—

The work which my associates and I have undertaken in reference to the transportation facilities of this city we believe is for the benefit of this community. This does not relate to the subject of electricity, I admit. Electricity, however, is a subject to which we have given quite a good deal of attention. I remember very well discussing the question of electromotive power and of cables with my friend Mr. Richards. He said to me, "Mr. Whitney, why do you want to talk to me of hell? Take away horses from our streets and you put us into hell." The few experiments that we have tried with electricity have not been successful. I was in hopes that my friend, Mr. Johnson, here, would explain the reason why. It is not that electric motors are not a success. It is true that the electric motors that we have tried here have not been a success; but that, I believe, is simply incidental. But the great difficulty attending the use of electricity on a street car is the difficulty of finding a proper storage battery. I apprehend there is no difficulty whatever in getting, sooner or later—and very soon—a proper motor which shall do the work. There have been very grave doubts whether any tractive power could be used in the streets when there were snow and ice. Some of the experiments that have been made in this city this year lead me to believe that it is possible to do so. Experiments which have been made in other cities seem to me to demonstrate its

practicability. Mr. Johnson tells me that even now there are discoveries which make it seem entirely practicable that the problem of the storage battery will be solved. I certainly hope it is so, for I hope the time is near at hand when something is coming to take the place of horses.

Mr. Johnson was asked if Mr. Edison could help them out in this matter, and replied that the electric motor could surely be applied to street railways. "The only question is as to the methods for conducting the electricity from the power station to the car. I am confident that you will soon see your cars run with electricity supplied by the electric motor.

Dr. Clarence J. Blake gave an interesting account of his early experiments with Professor Bell, and Professor Jacques said that within ten years the number of telephones had increased from one to 350,000, and long-distance telephoning was possible. Colonel J. H. Benton, Jr., and others spoke, and the club adjourned.

The West End Railway Co. has been for some time engaged in experiments in connection with electric cars, and to-day a trial trip was made with the Weston car, which has already made several trips. The car came in from Cambridge by way of East Cambridge, the inventor, Mr. William L. Stevens, and others, being aboard. On arriving at Post Office square the car was met by a few gentlemen who had been invited to witness the test, and ran through Federal, Franklin, Washington and Milk streets, back to the square. The car then ran to Causeway street and returned by way of Canal and Sudbury streets, continuing through Tremont and Boylston streets to Columbus avenue, where the speed was increased to ten miles an hour for a short distance. While running on a level the car moved smoothly, and there appeared to be no difficulty in going around sharp curves; but on steep grades there was not sufficient traction and the wheels would frequently slip.

The Western Union Telegraph Co. laid, about two years ago, two tubes containing wires through State, Washington and Friend streets to the Eastern station on Causeway street. These are the only underground wires used by the company in Boston.

About five miles of underground conduits are used by the New England Telephone & Telegraph Co., the number of ducts in the conduits varying from two to twelve. Each duct has, under the present system, 200 wires; but with the metallic circuits which are being introduced, only 75 wires can be held in each duct. One conduit now goes from the central station, at the corner of Pearl and Franklin streets, through Pearl, Congress, State and Exchange streets to Dock square; here it divides, one conduit going through Union, Endicott and Beverley streets to Warren bridge, while a spur line runs through Brattle, Court and Cambridge streets to Staniford street. There is a conduit from the central station up Franklin street to Washington, and a spur line runs through Arch and Chauncy streets, Harrison avenue, Beach, La Grange and Tremont streets to Ruggles street. There is also a conduit from the South End office to the Back Bay.

The joint committee on underground wires made a report at a meeting of the aldermen, December 19th last, the concluding portion of which is as follows :—

"The fact is now admitted in all the large American cities that the wires must ultimately be placed underground. The principal obstacles to the system have been done away with, and the main objection of the companies has practically reduced itself now to one of expense only. The cost of establishing the present overhead wire system has been excessive, and this expense will be practically a loss to the companies when the system is abandoned and the wires are placed underground. While it is also true that the first cost of placing the wires underground will be large, the cost of repairs and maintenance will, according to the testimony of experts, be much less than is required in the present overhead system. Your committee believe it would be unwise to compel the electric wire companies operating in Boston to place their wires underground in separate conduits, and that the city must either construct a subway for the reception of all electrical conductors, or contract with some conduit company to construct underground conduits of sufficient capacity to receive all surface wires in operation."

Mayor Whipple, of Brockton, Mass., on retiring from office, alluded to electric lighting.

"One of the most important improvements that have been made is the introduction of the Edison municipal system of street lighting, all naphtha and gas lights having been replaced by electric lights. By the adoption of this new system we are enabled to turn on the light in any section of the city at a moment's warning, in case of fire or any other emergency; and aside from the advantages gained, the introduction of the system adds much to the general appearance of the streets."

The Cambridge Electric Light Co. is replacing its present street lamps with those of the American system, and it is expected that the new lights will be ready for use next week.

An electric light was recently used to find a body under water, near Boston. It was first demonstrated by the United States government that the electric light could be used to good advantage in the deep. The government uses it effectively in the capture of fish, and the steamer Albatross, in the service of the Fishery Commission, is provided with a full equipment of lights to use for that purpose. The lights are incandescent, but the glass is much heavier than that used in lighting rooms. It is encased in a wire netting, which acts as a guard and prevents breakage. The net also acts as a trap. The light is connected with the dynamos with specially constructed cables. The fish, being attracted by the light, swarm into the net, which is then closed and pulled in. The specimens not wanted by the commission or the steward are restored alive to their natural element. The light can also be used in the recovery of dead bodies from wrecks, and is destined to be an invaluable aid to divers. It is said that some Gloucester fishermen contemplate using the light in their business.

A spirited horse that has a disagreeable way of bolting was made the subject of an interesting experiment recently at the veterinary school of Harvard University. Dr. Harrison of the school procured a battery, of small size, and extended two slight wires from it along the reins to the bit of a bridle. These wires terminated in small knobs. Then the electricity was applied to the horse, care being taken to use it in connection with the words "whoa" and "steady." The animal after a few experiments became docile, and his "bolting" ceased. He was tried under circumstances calculated to excite him, and the experiment proved perfectly satisfactory. The experiment is one of considerable importance, since, though it has been tried in France, it has not been performed in this country before.

Suits have been begun by the attorney-general against the Western Union Telegraph Co. to recover the state taxes for 1886 and 1887, amounting to $11,416.26 and $15,085.38. The allegations in these cases are substantially the same as in that now pending in the United States courts for the taxes of 1885, the details of which have been already published.

The signal service is making arrangements for giving warning of the approach of heavy snow storms sufficiently in advance to enable railway officials to make arrangements that will prevent delay to travel. These predictions, which it will be the aim of the signal service to furnish as early as thirty-two hours before the storm, will enable railway superintendents to expedite the movement of freight trains and to side-track those that it is evident cannot be brought to their destination. Observers are instructed to enter into communication with railway officials in their districts, and ascertain whether they desire these warnings by telegraph from Washington. Those who adopt this means will receive the warnings as soon as the local observers. Messages will be sent by telegraph to certain selected stations, and immediately upon their receipt observers will make every effort to inform the public through the press and by bulletins posted in conspicuous places of the approaching storm. Any person in the vicinity of a signal station who signifies his willingness to pay the cost of telephoning or telegraphing will be furnished these reports as soon as they are received from Washington.

The statement of output of telephones by the American Bell company for the month ended Dec. 20 herewith is given, together with a tabulation by months of the outputs for the fiscal year, and a comparison of the year's total with that of 1886:

December—	1887.	1886.	
Gross output	3,486	3,946	Dec. 460
Instruments returned	2,094	1,686	Inc. 408
Net output	1,392	2,260	Inc. 868

FISCAL YEAR ENDED DEC. 20.

	Gross output	Instruments returned	Net output
January	3,974	1,956	2,018
February	3,405	1,918	1,487
March	4,372	1,452	2.920
April	4,685	1,870	2.815
May	5,256	2,320	2,936
June	6,971	1,598	5.373
July	4,345	3,196	1,149
August	3,533	3,353	180
September	4,110	2,152	1,958
October	3,689	2,213	1,476
November	4,330	2,667	1,663
December	3,486	2,094	1,392
Year	52,156	26,789	25,367

YEAR'S OUTFIT COMPARED.

	1887.	1886.	Increase.
Gross output	52,156	42,306	9,850
Instruments returned	26,789	19.924	6.865
Net output	25,367	22,382	2,985

A good example for officers of electric companies may be noted in the dinner given on Dec. 21st by the management of the New England Telephone and Telegraph Co. to their division superintendents and managers of exchanges, at Young's hotel, in this town. About forty plates were laid. Previous to dining a conference was held, when the best methods of managing the offices and general business were discussed.

BOSTON, Mass., Jan. 16, 1888.

WASHINGTON.

Government Telegraphs in Congress; Various Schemes Proposed.—A Bill for the Relief of War Telegraph Operators.—Efforts to Introduce Electric Light in Government Buildings.—Electric Light Notes.—The Chesapeake and Potomac Telephone Co.—

Underground Cables.—President Green of the Western Union Telegraph Co. and Hon. Gardiner G. Hubbard give their Views on Postal Telegraphy, before the Senate Post-Office Committee.

THE opening session of the Fiftieth Congress brings back as fresh as the day they were introdued the long list of bills to transfer, in one way or another, the control of the telegraphing of the country from private hands to the general government.

Senator Edmunds was the first in the field with his old bill, to construct four trunk lines from Washington, to be extended from time to time as appropriations therefor may be made by Congress. The general control of the construction is placed in the hands of the engineer corps of the army, while the working and operation of the lines, as a part of the postal system of the United States, is put under the charge and direction of the Postmaster-General. Clerks, electricians and operators are to pass a civil service examination. Two million dollars are appropriated outright to initiate the undertaking.

The seventh section of the bill is so peculiar that it is given entire below:

"*Section* 7. That the Secretary of War is hereby authorized and directed, with the approval of the President of the United States, to construct or take and use all such machinery, appliances, devices and materials, not including telegraph lines owned by persons or corporations, whether patented or not, as shall be deemed necessary for the convenient and successful establishment and operation of said lines; and in case said secretary cannot, with said approval of the President, agree upon the value of such property, or any part thereof, or of any right or interest therein, the owner or owners of such property, or any right or interest therein, shall be entitled to file a petition for just compensation therefor in the Court of Claims of the United States, which court is hereby invested with jurisdiction to hear, try and determine the same, subject to an appeal to the Supreme Court of the United States; and the sums of money necessary to pay any such final judgments of said courts, respectively, are hereby appropriated out of any money in the treasury not otherwise appropriated; but no refusal of the owner, or any person or corporation claiming any right in any such property, to receive such compensation as may be offered by the Secretary of War, with the approval of the President, shall have the effect to prevent, hinder or delay the taking and use of any such property for the purposes aforesaid."

Senator Cullum's bill proposes to establish a postal telegraph on a rather more elaborate basis, and starts out with a four million appropriation and the same indefinite amount to pay the awards of the Court of Claims. He proposes ten trunk lines, viz: Washington to Portland, Me., Washington to Minneapolis, Minn. and Washington to Galveston, Texas; New York to Cleveland, Ohio, Pittsburgh to Topeka, Kan., Toledo, O., to Detroit, Mich., Chicago, Ill, to New Orleans, La., Chicago to St. Louis, Mo., Chicago to San Francisco, Cal., and from Chyenne, Wyoming, to Denver, Col. Stations are to be located at all first, second and third-class post-offices *en route*. The same provisions for construction and control are provided as in the Edmunds bill, except this bill provides a "Director-General of Telegraphs," with the rank and pay of an Assistant Postmaster-General. It also proposes the poles shall be of iron, of size and strength to carry twelve wires. Between Washington, New York and Chicago eight wires, and on the other routes four wires are fixed as the initial number. The rates for the transmission of messages are also fixed at ten cents for twenty words or less, and five cents for each additional ten words or fraction thereof when the distance is less than five hundred miles, and five cents additional for each two hundred and fifty miles or fraction thereof. Press rates are fixed at 75 cents per hundred if sent during the day, and 35 cents per hundred if sent during the night. Drop copies 50 cents for day and 25 cents for night. Manifolding five cents per hundred words. Why this discrimination is made against the press will probably come out in the course of debate. This bill goes further than that of Senator Edmunds, and applies the civil service rules to those employed in receiving, transmission and delivery of telegrams.

The House of Representatives, being a new body, consumed some time in getting ready for business, and it was not till the 4th of January that an opportunity was afforded for the introduction of bills.

Mr. Rogers, of Arkansas, led the telegraph reformers with his bill of the forty-eighth Congress, which in that Congress got so far as to be reported from the Post-Office Committee to the House. This bill fixes the rates between New York and Philadelphia, Baltimore, Boston and Washington, and such other points separated by short distances as may from time to time be designated by the Postmaster-General, at 15 cents for 20 words. Under 2,500 miles, 25 cents and five cents for each additional 250 miles. No rates to exceed 50 cents. Night service, half price, except when the 15 cent service prevails—which is not reduced. Press matter 75 cents per hundred for day and 35 cents for night transmission. This bill contains one very proper clause, viz.: "Telegrams shall be privileged communications in law to the extent that sealed letters now are." The money order system is made applicable to this postal telegraph.

Having thus created a postal telegraph system he proposes after advertising for proposals to contract with the telegraph company making the lowest bid for the performance of the service as provided in the bill.

Mr. Weaver, of Iowa, takes a more comprehensive view of the subject. He ignores the feeble efforts that have been made by private capital to establish telegraphic communication, and proposes to connect by such a number of postal telegraph wires as will meet the requirements of the people for business and personal correspondence "All the post-offices of the country south of the northwest boundary of Washington Territory, having a population of four hundred (400) inhabitants." And the Postmaster-General is authorized to connect such other minor post-offices as he may deem proper, the object of the bill being to ultimately and as speedily as practicable reach every post-office in the country.

The rates are made uniform at 10 cents for 10 words, and five cents for each additional 10 words. Press not exceeding 20 cents per hundred.

An appropriation of $25,000,000 is proposed as a *starter*.

Mr. Anderson, of Kansas, comes back with his bill of the last Congress, proposing three trunk lines, with numerous branches, as follows: Bangor, Me., *via* Boston, Albany, Buffalo, Cleveland, Toledo, Chicago and Madison, Wis. New York *via* Philadelphia, Pittsburgh, Columbus, O., Indianapolis, St. Louis, Kansas City to Salina, Kansas. Baltimore *via* Washington, Richmond, Raleigh, Augusta, Atlanta, Montgomery, Mobile, New Orleans, Houston, Austin to San Antonio, Texas. It is proposed to connect with all land grant lines on the terms embraced in such grant, and such other lines as may have or shall hereafter accept the terms of the act of July 24, 1866.

The Postmaster-General may construct air or underground lines by contract or may through the Secretary of War require the work to be done by the signal corps.

The rates in this bill are fixed at 30 cents for 10 words and three for each additional word, but the Postmaster-General may reduce the rates where there are competing lines. Ten millions are appropriated out of the treasury to start this scheme.

Mr. Raynor, of Maryland, proposes by his bill to create an inter-state telegraph commission of three members, to be appointed by the President, with a salary of $5,000 each per annum, to lay out, build and construct trunk lines of postal telegraph with power to control rates for the transmission of despatches—and appropriates eight millions for the carrying out of the plan proposed.

Mr. McComas, of Maryland, proposes a more novel scheme. He proposes that after July 1, 1888, telegraphic messages may be deposited at any place in the United States where letters are deposited, prepaid in postage stamps. Meantime the Postmaster-General shall advertise for facilities for the transmission of despatches and if the aids of existing corporations are not satisfactory the Postmaster-General may advertise for proposals to construct the necessary lines. The rates fixed for the transmission are one cent a word, counting date, address and signature—with a deduction to the press of 40 per cent. above 100, and under 500, and 50 per cent. on all over 500 words, or postal wires may be leased to newspapers. Whenever telegrams are left at post-offices where there is no telegraph they are to be forwarded to the nearest postal telegraph office.

Mr. Warner, of Mo., has reintroduced the Logan bill for the relief of telegraph operators during the war (H. R., 1,607). It provides for a certificate of honorable discharge on application to the Secretary of War, and the same rights of homestead entry and pensions as are now or may be allowed by law to others who served in the army. It also provides that appropriate medals shall be struck and presented to those who served as operators and builders in the war. With the medal clause, which will invite opposition, stricken out, the bill which has been modified to meet the views of the war department ought not to meet with any serious opposition.

Repeated attempts have been made to introduce electric lighting into the national capitol, but up to the present time they have proved unsuccessful. At the beginning of the Forty-seventh Congress the American Electric Light Co. obtained permission to put in at their own expense an experimental plant to light the restaurant, some of the halls and some of the rooms with their incandescent lights. The exhibit was quite creditable, but they failed to secure an appropriation for an extension of their work or to repay them for their outlay, and the effort was abandoned.

Two years ago the Edison people attempted, by an elaborate effort made on the same terms, to convince the Senate of the superiority of the electric light, and succeded so far as to get a clause in an appropriation bill to pay for the plant then in, and for its material extension, but the House struck it out, and in conference the clause was framed in such ambiguous language that no one would take the responsibility of acting upon it, and neither was the money paid nor the order for the extension given. Disgusted with their experience, the parties interested, after an expenditure as I am informed, of over $6,000, have withdrawn their plant.

At the House end the United States companies, parent and local, essayed to give a more desirable light, and put their lamps in the cloak rooms, and a few elsewhere. Owing to some mis-

understanding, growing out of the divided responsibility, their exhibit was not as satisfactory as it could and should have been, and they failed to secure recognition, for which, however, no strenuous exertion was made.

Undaunted by the fate of their predecessors, the Sawyer-Man company this year obtained permission to introduce their system on similar terms—*i. e.*, the work to be done without expense to the government or damage to the building, and early in November commenced wiring both wings of the capitol. They have arranged their wires for a very large number of lights in the cloak rooms, halls, restaurant, folding-rooms, offices and committee rooms; put in an engine and dynamo for each wing, and put up their wires in a most thorough and permanent manner, as if they intended to stay I have no data as to the expense to which they have gone, but it is many times in excess of any former effort in this direction. If they fail, their failure will be sufficient to deter others from undertaking so hazardous an enterprise. The work will be finished and the lights started early in February.

The United States Electric Light Co. (local) having secured the control of the Edison incandescent system for the District of Columbia has established an extensive central plant at the corner of 13½ and B streets, and are putting in eleven engines with a combined power of 1,400 h. p., sufficient, it is estimated, for 10,000 incandescent and 500 arc lights. They now light the principal business streets with their arc system (Thomson-Houston) and are constantly extending their light to the minor streets.

Their incandescent lamps have, since the plant was started, taken the place of the arc when used in business places, and have been substituted for the Weston high tension lamps, formerly used in the treasury department. A thousand lamps have just been put in the bureau of printing and engraving, and the entire state, war and navy department building is being wired for the introduction of the Edison lamp. The Western Union office has also been wired, and the lamps are to be started in a few days. Orders have been given for numerous other public and private establishments, and are being filled as rapidly as possible.

This company has been at much expense in laying cables underground, having tried a number of different manufacturers, and in every case where they have attempted to use a high tension current the cables have failed. Repeated efforts to take up and repair have also failed, and those cables are now abandoned. Still they are laying new cables for their incandescent lights, under the belief that a lower tension will not destroy them. Incidental to their lighting system, the company proposes to furnish motors to the various mechanical industries in their immediate neighborhood to be used during the day when the power is not needed for lighting purposes. It is believed this can be done to the profit of the company and the manufacturers.

The Chesapeake and Potomac Telephone Co., which embraces this city and Baltimore, have been more successful in the use of cables, although they find the retardation of the current somewhat annoying. They extend their cables from the central office through the central part of the city and thence by air lines to subscribers. They have adopted the plan of using two cable wires for each air line, grounding the return wire where it leaves the cable. The effect of this it is claimed destroys the induction and makes the circuit approximately a metallic one.

This company has just declared its usual quarterly dividend of 1¼ per cent., and laid aside a handsome sum for construction account. It is now putting up a new office in Baltimore, corner St. Paul street and Bank lane, to be six stories high, strictly fireproof, and costing, with the ground, $120,000. It will be ready for occupancy about midsummer. So satisfactory has the cable service been here that they will, during the coming season, expend a large sum in that direction in Baltimore, where it is proposed to lay from 6,000 to 8,000 miles of wire underground.

A question as to the rights of these underground cables has arisen here, the solution of which will be of interest. Under a permit, or rather a *mandate* of the commissioners, this company, some time since laid their cables under the sidewalk, alongside the curb, on 15th street, including the frontage of the National Safe Deposit Co. Subsequently the Deposit company obtained a permit to build a vault under the sidewalk. During the excavation the wires were temporarily stayed up as best could be, but when the flagging was to be laid the removal of the wires was demanded and their forcible displacement threatened. The telephone people prayed out a temporary injunction, and the matter is now before the court for a final adjudication.

The National Board of Trade, at its recent session in this city, adopted by a vote of 26 to 9 a resolution, "That the usefulness of the post-office department should be extended in the direction of telegraphic communication; and we urge upon Congress the earliest favorable consideration of this question." The telegraph appears to be getting along very well in private hands just now, and the necessities of the public reasonably well met at lower rates of charges than ever before, while the coal traffic is a good deal disturbed. Perhaps these gentlemen could see a way for the government to assume control of the coal mines, and give to all their fuel at a minimum charge—say $3 or $4 per ton. Then in the progressive spirit of the postal telegraph schemes, they could take the iron furnaces, which are so intimately connected with the coal productions, and so go on with the iron and steel interests until our watch-springs and needles bore the stamp "U. S.," and every woman in the country was guaranteed a needle that would not cut in the eye or snap at the point. What a glorious day it will be when a paternal government gives employment to everybody and furnishes everything they want at prime cost!

Messrs. Norvin Green and Gardiner G. Hubbard have been before the Senate post-office committee and given their views upon the postal telegraph, reports of which have been given by the daily papers. The older members of the committee were indisposed to give them a further hearing, as their tales had been thrice told, but, like the girl who got married because the children had never seen a wedding, they consented to a hearing out of consideration for the new members.

WASHINGTON, Jan. 19, 1888.

CHICAGO.

Successful Starting of the City Electric Light Plant on the Water Front.—Apparent Cessation of Hostilities against the Gas Trust.—The St. Louis Gas Trust.—The Brush Light Station at St. Louis Damaged by Fire.—Unexpected and Unaccountable Gas.—Incandescent Light Competition at Chattanooga, Tenn.—Mr. C. H. Wilson as Superintendent of the Chicago Telephone Co.—Corporation Counsel Green's Opinion on Telephone Licenses.—Resolution of Counsel to Refuse Further Permits to the Telephone Company.—Mr. J. E. Zeublin Succeeds Mr. C. H. Wilson in the Central Union Telephone Co.—Another Indiana Court Decision Adverse to the Central Union Telephone Co.—The Chicago Electric Club.

THE river plant, which is the name given to the electric light plant owned and operated by the city for lighting the Chicago river and the bridge approaches. was successfully started on the 24th of December, with only 12 lights. Since that date the number of lights in operation each night has been gradually increased, until now there are lighted each night 30 lights extending from Polk street to the lake on the south side of the river. The effect of the light exceeded even the expectations of Professor Barrett and Mayor Roche, who were the original promoters of the scheme. The river is lighted so well as to render navigation as feasible at night as during the day, and it is intended to give the vessels practically free way up and down the river from 12 midnight to six in the morning, thus lessening the obstruction to navigation of the river, and at the same time keep the bridges closed for street traffic during the day. Mayor Roche has recommended to the council that the system be extended by the installation of a 125 light plant at the west side pumping station.

Judging from the votes which have been taken in the city council lately on matters relating to the Gas Trust it would seem that war had ceased for some reason. No action has been taken so far in the matter of the *quo warranto* proceedings which attorney-general Hunt was instructed to bring.

Another plan for defending the city against the alleged extortions of the Gas Trust has been proposed by alderman Clarke. His plan is for the city to purchase an incandescent electric light plant and substitute a 32 c. p. incandescent electric lamp for each gas burner now used on the streets. This scheme is ably presented by alderman Clarke, whose connection with the Edison company puts him in possession of useful facts and figures for his purpose.

The Gas Trust, of St. Louis, is undergoing an investigation at the hands of the city council, which succeeds in bringing to light many interesting facts regarding the methods of the Trust. The Laclede Gas Co. is the only one of the companies doing business in St. Louis, which has not joined the Gas Trust of that city. This fact and the further fact that the Laclede company has practically decided to go into the business of electric lighting may have had something to do with the decline of over 40 per cent in the market value of Gas Trust certificates.

The station of the Brush Electric Association, of St. Louis, was damaged by fire on the 6th of this month. The damaged machinery was promptly replaced, and the business of furnishing lights was continued with little interruption.

Much interest and discussion has been aroused by an unexpected flow of gas from a water pipe leading from the lake into a brewery in the southern part of the city. Many believe it to be natural gas, but analysis shows it to be very different from the natural gas of Ohio and Pennsylvania. However, it has continued to burn steadily for several weeks now, and preparations are being made on a limited scale to make use of it. This discovery has led to considerable prospecting and seems also to have been the means of bringing to notice the fact that the artesian well in the Leland hotel furnishes a copious supply of gas as well as water. At least one other gas producing well has been found within the city; and it is claimed that large flowing wells have been found within piping distance. The development of the incandescent gas burners gathers interest in connection with the discovery of natural gas, and with the prospective franchise of a fuel gas concern which proposes to manufacture fuel gas in the Illinois coal region, at a cost of one cent per thousand feet, and pipe it to Chicago. It is

exciting particular interest in the minds of the stockholders of the Chicago Edison company, whose plant is proceeding slowly to completion.

At Chattanooga, Tenn., two incandescent electric light systems are contending for supremacy, and the contest has unusual interest because it is between alternating and continuous current systems. The Hauss continuous current system has now some 2,500 lights in operation. The Westinghouse has about 650—the entire capacity of the dynamo which is now in operation.

Mr. C. H. Wilson, the recently appointed superintendent of the Chicago Telephone Co., assumed the responsibility of his new position, January 1st. His experience with the single cord system of multiple switch-board at Columbus has been so satisfactory that he will probably decide on the introduction of a similar system in Chicago. He has changed the location of the operating room in the new telephone building from the third to the top floor and proposes to go further than was originally intended, in the direction of consolidating the business, and transfer to the new office the business now done in three exchanges.

Judge Green, corporation counsel, has submitted an opinion on the question whether under the ordinance now pending before the council the city has the right to license telephones. The ordinance now pending, it will be remembered, is the one instructing the Commissioner of Public Works to refuse permits, which are necessary for laying wires, until the telephone company should produce a receipt, signed by the city collector for the sum of $10 for each telephone in use in Chicago. Judge Green's opinion is that the power to license is inhibited by the fact that the occupation is not directly or impliedly enumerated in the general incorporation law, and that it is not within the boundaries of the police power, and that it does not come within the spirit or letter of the law authorizing the exercise of that power for the protection of the lives or health of the citizens, or the preservation of good order and public morals. He is therefore of opinion that the ordinance is illegal. But he claims that unless the telephone company has the explicit consent of the city to operate its lines upon or under the streets, such occupancy of the streets could not be valid, in view of the strict provision of the statutes requiring the consent of the city for that purpose.

This opinion of Judge Green, together with his recently submitted opinion to the effect that the franchise under which the company is now operating is invalid, has made conspicuous the weak point in the position of the telephone company. That the council were not slow to adopt the suggestion embodied in the opinion is shown by the following resolution, adopted at the same meeting at which the opinion was read :

Resolved, That the Commissioner of Public Works is hereby directed and instructed to issue no further permits to the Chicago Telephone Co. to use the streets and alleys of the city of Chicago for telephone purposes until the further order of the council.

Mr. J. E. Zeublin, recently and until the consolidation of the Baltimore and Ohio Telegraph Co. with the Western Union Telegraph Co., general superintendent of the former company, succeeds Mr. C. H. Wilson as superintendent of the Ohio division of the Central Union Telegraph Co.

A recent decision of Judge Ventor, at Lafayette, Ind., adds one more defeat to the long list which the Central Union Telegraph Co. has suffered in that state. Judge Ventor holds that under the well-known Indiana statute, relating to telephone rental rates, a company doing business in that state is bound to furnish every applicant with a telephone and connections at the statutory rate. The telephone company set up in its answer, a demurrer to which is sustained by Judge Ventor's decision, that it was not engaged in the business of renting telephones or of supplying private wires or private telephones to anyone; that the only form in which it undertook to serve the public was by means of what is known as the public toll system, under which the company established agencies or public stations at the residences or business houses of all persons to whom it supplied telephone service, and that all such persons were the company's agents, and that all individuals on equal terms might, by paying five cents for each connection, use these telephones at such stations. The court held that while the company might perhaps legally conduct business in this way, yet, as it was engaged in a general telephone business, it was, nevertheless, bound to supply every applicant for telephone connections and facilities at his residence or place of business with a telephone, and the necessary apparatus and facilities for placing him in connection with all the local patrons of the company, at $3 per month, the statutory rate.

The Chicago Electric Club gave a very enjoyable entertainment and lunch on the evening of January 7th. The members were enthusiastic in their praise of the arrangements made by the entertainment committee, of which Mr. H. Ward Leonard is chairman. The entertainment consisted of a musical programme with an intermission for lunch, and it was a very agreeable departure from the usual formal banquet. At the regular meeting, held on the 16th, Mr. C. A. Brown read a paper on "Our Patent System and its Proposed Amendment."

CHICAGO, Jan. 19, 1888.

SAN FRANCISCO.

A Visit to the East.—Chicago Street Cars.—Admirable Organization of the Western Union Service in Chicago, under Col. Clowry.—Personal Changes in Western Union Service in California. Electric Light in the San Francisco Prison.—Affairs of the Postal Telegraph Co.

YOUR correspondent has been absent from this coast for a considerable period, during which he has journeyed and sojourned in the east; at least east as far as Chicago.

The City of Chicago presents a fine field for an electric railway and yet there is none. The street car system is ante-deluvian and abominable. Their cable system is away behind, and inferior to ours, and their horse cars make walking a luxury. It is true, that Lethes pool (the Chicago river) is a drawback to good cable systems, but should be none to electric roads. And yet in other respects Chicago leads the world: As far as the Western Union management is concerned, it certainly does—Col. Clowry has surrounded himself with a staff the like of which is not in the length and breadth of this great continent. Messrs. Summers, Bristol, Tubbs, Lloyd (and the minor staff under Lloyd) make labor a pleasure. The writer desires to record the fact that in his quarter of a century of experience, the past six months in Chicago has been made the pleasantest he has spent in a telegraph office (and he was no exception to the general treatment of operators). Mr. Lloyd is very able and energetic, with the finest disposition and equanimity of temper and clear judgment. During the writer's stay in Chicago, Col. Clowry and Messrs. Summers and Bristol were on this Pacific Coast overhauling things in general, and infusing new life into the management of San Francisco and other places in California. John McRobie was taken from the Board of Trade office in Chicago and made manager of San Francisco, with full control. Geo. D. Thomson, night chief operator of Chicago, was made chief operator of Los Angeles. Mr. McRobie's appointment was a God-send to San Francisco. The cry of down-trodden and outraged operators was heard and answered. He will have a herculean task to evolve order out of chaos, and chaos at best it was—but, if any man can do it, McRobie is equal to the task.

Col. Clowry seems to have appreciated the fact that Mr. Jaynes was over-worked and that the rapid growth of his division diverted his attention from minor details and local necessities, hence, he ordered F. H. Lamb from Portland to San Francisco to act as assistant superintendent to Mr. Jaynes.

Gen. John McComb, late editor of *The Alta-California* and now warden of San Quentin prison, appreciates the necessity of illuminating the outer and inner yards of the prison by electric lights; establishing a plant solely for the prison, to be operated by prisoners (there are a few *electricians* and *operators* there). How would it be in the event of a revolt if the electricians were in league with the Jack Cades? The idea is a bright one.

The Postal company are still struggling and wrestling with local Northern business; no move having been made to build or extend their lines in any other direction. It is just a year ago since in this correspondence the advisability was pointed out of building south and east. Assurance was given by Mr. Henry Rosener, a director—that they would, within a few months, begin such construction—and yet they have not, nor do they evince any intention to do so, thus giving a corroboration to the rumor that Mr. John W. Mackay has no longer any financial interest in the Pacific Postal Telegraph Co.

His superintendent was discharged and a Canadian put in Robeson's place. This would look as if the Canadians were running it. It is to their interest to have it known that Mr. Mackay is still connected with that company, because two-thirds of their business is secured through Mr. Mackay's popularity, when every circumstance points to exclusive Canadian Pacific control. If it is once authenticated in this city the toleration and forbearance of the public will cease and business necessity will supplant personal friendship, and the Postal will lose by the confirmation of the rumor.

SAN FRANCISCO, January 17, 1888.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

THE REIS TELEPHONE CONTROVERSY.

[85.]—The experiments with the old and original instruments of Philip Reis were made by me, in this country, during the summers of 1885 and 1886, and the first account of them appeared in

the *Scientific American* for Nov. 28th, 1885; later on, by correspondence with Professor Edwin J. Houston, they were published in *The Journal of the Franklin Institute* for January, 1887, and July, 1886. In this correspondence I have fully stated the nature and results of my work, and, taken together with the published records of my testimony in the Overland Telephone cases, they furnish all the information necessary for any who may care to review the subject. I refer to them simply at this time to answer certain charges made by Dr. Stein in your issue of July, 1887, one of which is that I misstated in my testimony on Oct. 15th, 1885, when quoting from the *Industrie-Zeitung*, by leaving out certain important words, viz.: "It was impossible, with the apparatus as then constructed, to transmit spoken words." Any one who will take the pains to read the context will plainly see that the question which I was then and there required to answer had reference solely to *musical quality*, and not to *articulate speech*. The quotation was properly and rightfully restricted to such parts as referred to "*quality*"; further on, in the same answer, I quote from the annual report of the Physical Society of Frankfort-a-M., 1860–61, a paragraph in reference to articulate speech, where *quality* enters in as an explanation given by Reis himself why his instruments reproduced "the consonants pretty distinctly, but the vowels as yet not in an equal degree." (Amer. Bell. Tel. Co. *vs.* Overland Tel. Co. of N. J., vol. 1, Defend's ans. and proofs, page 704, interrog. 4.) The more serious charge that I changed the apparatus itself, so as to cause it to conform to later telephone inventions, can have for its basis no foundation whatever in the minds of those who read the testimony from an unprejudiced standpoint, the so-called fundamental change being "*the loosening of a binding post*, which had pressed the contacts of the transmitter too tightly! The simple facts are that the metallic strip which supports one of the contacts had become bent where the binding post passed through it, and, in consequence, the contacts were pressed together so as to form *a tight joint*, and *no variation of the electric current whatever was possible* until the pressure at the joint was relieved; this was done by loosening the binding post a little. I maintain that the mode of operation of the instrument was not thereby changed to conform to more modern inventions; on the contrary, the disposition of the contact points was *then* such that "breaks" would naturally occur for all the *principal* vibrations of the membrane—a condition which was insisted on by counsel as the original disposition of the parts by Reis himself; and that "breaks" *did* occur, approximately equal in number to the principal vibrations, was evident in my experiments by the humming sound of the electrodes, as they broke contact, and the succession of electric sparks (*The Journal of the Franklin Institute*, July, 1886, page 59). I do not ask the privilege of your columns to indulge in any personal controversy, as I might be justified in doing from the nature of the charges made; but I prefer to leave the experiments open, as they always have been, to the scientific public, to verify by practical tests—which, in my own estimation, would be a far better proof of the verity of my statements than any written argument possibly can be.

The other points in the controversy, referring to myself, have been fully answered by Professor Houston, and I need not refer to them here.

The investigations of Mr. Kintner have been of especial interest to me, as pointing to a conclusion which I myself reached from practical experience with telephones of many kinds, viz.: "that articulate speech, sufficiently good for commercial purposes, can be produced by *makes* and *breaks* in an electric current, if properly timed as to their duration," etc. In one of my published letters in 1886, I state that it is my belief that articulate speech can be thus transmitted, when such breaks are timed and spaced by the voice itself. I shall look with additional interest for the demonstration of this principle, which Mr. Kintner promises to furnish in his admirable articles upon the subject now appearing in THE ELECTRICAL ENGINEER.

So far as the Reis instruments are concerned, I am inclined to agree with Professor Dolbear to this extent—that the transmitter is an automatic device, and is subject to the intention of the operator only to a limited extent. As regards the receiver, my own experience confirms Professor Dolbear's statements that speech has and can be transmitted and received by a Reis transmitter and Reis receiver in the same circuit. It cannot be disputed that, in any magneto-receiver, articulate speech is perfectly reproduced by *the iron core, and its helix of surrounding wire* (saying nothing of the diaphragm). Such a receiver is the Reis knitting-needle receiver, pure and simple; and it reproduces, faithfully and accurately, whatever variations in the electric current are produced at the transmitter. Granted that the Reis transmitter transmits a single word, that word must of necessity be reproduced by the Reis receiver; theoretically it is easy enough to see this, and the fact is self-evident without demonstration; but the courts require a demonstration which shall convince the most obdurate by the sense of hearing alone; and the volume of sound given out by a Reis receiver being very small indeed, there will be those in almost every public trial who will say they could not hear it.

Starting with a potential of at least five or six volts, and giving the electric current at transmitter as wide a range of variation as possible, the receiver has, in my own hands, spoken loud enough to be heard by any one. The real difficulty here lies, as we all know, in effecting a wide range of variation in resistance with platinum alone. It is comparatively easy with a few grains of carbon, and *even lead peroxide*, to do this, as I have shown in a paper reported in the London *Electrical Review* for Nov. 11th; but in the case before us we are limited to platinum, and hence great skill and care have to be exercised. JNO. R. PADDOCK.

Stevens Institute of Technology, Dec. 12, 1887.

ELECTRO-MAGNETIC SEPARATORS.

[86.]—Since the publication of my second article on the "Uses of Electricity in Mills" in the December issue, page 487, in which reference was made to the greater strength of electro-magnets as adapting them for more efficient use than permanent magnets in applications where magnets are employed to separate bits of iron from the stock in various processes of manufacture, I have learned that electro-magnets charged by a small Mather dynamo especially constructed for the purpose have been used with especial success over the permanent magnets formerly used in separating iron from the stock in process of paper manufacture.

C. J. H. WOODBURY.

Boston, Mass., Dec. 22, 1887.

LIMITATION OF UNITED STATES PATENTS BY FOREIGN PATENTS.

[87.]—In the U. S. patent law limiting the term of a patent taken out in the U. S. by the expiration of the foreign patent, this reading occurs (Rev. Stat. 4887):

"But every patent granted for an invention which has been previously patented in a foreign country, shall be so limited as to expire at the same time as the foreign patent."

The courts have decided in a large number of cases that the American patent must expire coincidently with the foreign one. As it is well known that the most important American patents on the incandescent light have expired under this law, have not the patents of the Bell Telephone Co. become null and void, by the decision of the Commissioner of Patents, of Canada, who declared the Bell patents void in Canada some months ago for failure to comply with the law?

I. H. DAVIS,
Dorchester, Mass.

January 10, 1888.

[The Canadian telephone patent was issued *later* than the U. S. patent. The duration of a United States patent is limited by the *expiration* of the *term* for which an *earlier* foreign patent has been issued. The *voidance* of a foreign patent has no effect upon the period of an U. S. patent. As stated by our correspondent, the Canadian Bell Telephone patent was voided—it did not expire.—ED.'S ELECTRICAL ENGINEER.]

LITERATURE.

REVIEWS.

Management of Accumulators and Private Electric Light Installations: A Practical Hand-book. By SIR DAVID SALOMONS, BART., M. A., A. I. C. E., M. S. T. E. Third edition, revised and enlarged. London: Whittaker & Co., and New York: D. Van Nostrand.

Sir David Salomons evidently does not approve the too common practice of grinding out successive editions from old "plates," just because they are handy. The present edition is even more radically improved, as compared with the second, than was the latter as compared with the first. In fact, the author has practically made an entirely new book, much better, both in scope and in substance. He has wisely concluded to cut a deeper furrow through this new fertile soil, and in order to do so, he has enlarged the title and the compass of the book, which has grown from 31 to no fewer than 146 pages.

The work is divided into two parts, as the title would of itself indicate. Each part has, moreover, been sub-divided into chapters, and some 28 illustrations have been introduced in the text, in addition to the frontispiece, illustrating the interior of Sir David Salomon's own accumulator house at Broomhill, his country seat. These features make the work far more comprehensive, convenient and clear than was the case with the previous editions.

Considering the very general attention which the applications of electrical storage are now attracting and also the lamentable meagreness of the literature of the subject, a practical work like this one, setting forth the teachings of experience—the things of all things most desirable—will undoubtedly be well received by the majority of electricians, to whom it will be very useful, if not indeed quite indispensable.

It is probably not asserting too much to say that there is no

person more competent than Sir David Salomons to write on the subject of the handling and management of accumulators, for it is doubtful if anybody could be found whose experience in this field is so comprehensive. He has done most valuable missionary work in studying what are sometimes called the vagaries and idiosyncrasies of the storage battery, his efforts dating from 1882, when the first storage batteries were placed upon the market, until the present day. Sir David was, it is true, well qualified for this work by combining, as he does in a happy manner, those four requisites—the leisure, the means, the facilities, the ability—which are so highly important in dealing with matters involving research and experiment. The last chapter of his work recounts, in an interesting manner, the transformations made in his own installation at Broomhill since 1882.

The $10,000, which he admits his futile experiments alone to have cost him, doubtless cover many severe disappointments; but it is encouraging to learn that these experiments have not been in vain, since they have enabled him to find remedies for many, if not quite all, the troubles which formerly beset the storage battery. It is, to say the least, a highly favorable sign of a good future for the storage battery to find Sir David's faith in it remain unshaken by his experience.

In expressing our opinion that Sir David Salomons is much more adept in the practice of ferreting out facts than in the art of recording or classifying them, we do not wish to detract in the least from the value of his highly meritorious work, but to imply rather that the author has not utilized to the highest advantage the rich stock of material which his experiments and observations have furnished him. The present edition, as did those preceding, suffers from numerous inaccuracies of diction and little grammatical faults, which suggest that a little careful editing would have been of great benefit. Moreover, the author does not seem to have found, in every instance, that happy way of stating facts which makes their implication quite clear to the reader. For instance, on page 62 he confuses electromotive force with difference of potential in the following sentence: "When the plates are sulphated, the internal resistance of the cells is greater, and the E. M. F., for daily use, is much lower." The same error is again made on page 111, in the statement that when a shunt-wound dynamo is short-circuited at its terminals, "practically no E. M. F. exists, and no current passes." On page 82 the author assumes the "friction load" of an engine to be constant, whereas it is in reality only approximately so, as engineers well understand. These, and a few other errors that appear in the book, should be carefully weeded out in succeeding editions. It is to be hoped that the author will cover yet more ground in the next edition. There are many topics which he has left untouched, and which really would be well entitled to a chapter each. Sir David Salomons has doubtless enough information to give us a "practical treatise" instead of a hand-book next time, and it is greatly to be hoped that he may do so.

Elementary Text-Book of Physics, by PROFESSOR WM. A. ANTHONY and PROFESSOR C. F. BRACKETT. New York: John Wiley & Sons, 1887.

Seven chapters of this work, embracing 130 pages, are devoted to electricity and magnetism under the following heads, viz.: I. Magnetism. II. Electricity in Equilibrium. III. The Electrical Current. IV. Chemical Relations of the Current. V. Magnetic Relations of the Current. VI. Thermo-electric Relations of the Current. VII. Luminous Effects of the Current. As might be expected from the limited space devoted to such extensive subjects, the treatment of magnetic and electric phenomena is brief and imperfect. The theoretical side of the subject-matter alone is considered, and the text consists mainly of definitions and resultant formulæ which appear to be anything but elementary. While this portion of the book may serve a useful purpose in the way of suggesting to teachers a course of study which may be advantageously enlarged upon, to the average student or practical worker it can have but little value, since there are already other works which cover the same ground in a simpler and more thorough manner.

CATALOGUES AND PAMPHLETS RECEIVED.

The "C & C" Electric Motor Co. have issued a pamphlet that is not only useful but extremely dainty. It is entitled "Some Cuts of "C & C" Motors and Apparatus." The cuts are uncommonly handsome, and exhibit motors, batteries and several useful applications of the motors. There is just text enough—and no more—to indicate and identify the objects shown; rather a good feature in circulars of this kind, which commonly contain more letter-press than busy people will read. The illustrations in the "C & C" circular are so fine and clear as to furnish all the description needed.

The Electric Water Protective Co., 713 Broadway, New York, send us a small pamphlet setting forth their readiness to furnish electric protection against water overflows. Their apparatus acts automatically to shut off the flow of water before damage is done. The utility and desirableness of such a protection are very obvious, and will no doubt be fully appreciated by owners of large buildings, as well as ordinary householders.

ELECTRICAL NEWS AND NOTES.

THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

MEETING OF JANUARY 10, 1888.

The President, Mr. T. Commerford Martin, took the chair, and said—The subject before us this evening is of a very interesting nature. The paper is by Mr. Willard E. Case, of Auburn, N. Y., and is entitled "Electric Energy from Carbon without Heat." In the absence of Mr. Case, Mr. Mailloux will read the paper.

(Mr. C. O. Mailloux then read Mr. Case's paper. See page 50.)

Mr. Mailloux—Mr. Case also favored us by sending a sample of the battery, which you have here. (Referring to a battery which stood upon the table.) It consists of a porous cup in which the graphite, in lumps, is placed, and outside of which is a sheet of platinum. Sulphuric acid, of the greatest density obtainable, chemically pure, is placed in both the inner and outer vessel. As explained in the paper, in order to render the sulphuric acid active, Mr. Case puts chlorate of potassium into the outer vessel, which gives it a light wine color. I have brought a little galvanoscope, which I have calibrated for the purpose, so that it gives a rough indication of the voltage of the battery. Each division represents $\frac{8}{10}$ of a volt; and when I close the circuit, you will see that it gives a deflection which is about 14 degrees. That would be equivalent to about $\frac{7}{10}$ of a volt. I think that Mr. Case states that the electromotive force of his battery is between $\frac{7}{10}$ and $\frac{8}{10}$ of a volt; but unfortunately, as you notice, the electromotive force falls very rapidly, owing to polarization. You will notice it is now falling. It is now only 12 degrees. It seems to stay there better. But if I let it rest a little while, it comes to more nearly the full strength, though not quite.

The President—You have heard this very interesting paper read. It is now open for discussion, and it seems a subject fertile enough to elicit a very full treatment on this occasion.

DISCUSSION.

Mr. Mailloux—I might state for the information of the members, that Mr. Case states, in a note sent with the battery, that the internal resistance is about $2\frac{7}{10}$ ohms, and that when placed on short circuit it gives, approximately, a quarter of an ampere for a short time. He adds, by way of explanation: "You understand I am not showing a practical invention; simply showing a new principle, which may be developed." I think you will all agree that undoubtedly there is here a wonderfully interesting principle.

A Member—Will you please give us the calculated electromotive force?

Mr. Mailloux—The calculated electromotive force of this form of cell is not given. Mr. Case simply states the observed electromotive force, which is $\frac{8}{10}$ of a volt. The calculations that he made, which I put on the blackboard, were merely the efficiency of the combination, of which heat was the active element. He gives the energy of combination—yes. Carbon and oxygen combined to form carbonic acid, so that the carbon is completely oxidized, give 9,624 foot-pounds per grain equivalent, or 2.0924 equi-volts. You will observe that that is our friend Sprague's nomenclature, which will have to be further elucidated in order to be intelligible. As I am not a disciple of Mr. Sprague, I would like to have somebody else explain it.

Mr. T. Wolcott—I would like to ask why the cell polarizes so quickly. As I understand, the oxidizing liquid is in contact with the platinum. It ought to act, I should think, like the chromic acid in a Poggendorff cell, to oxidize the hydrogen; or is it hydrogen that polarizes it?

Mr. Mailloux—Mr. Case states that the polarization can be prevented by mechanical means; so that it is probably due to uncombined chlorine.

Mr. J. Wetzler—I was about to suggest that the polarizing might be brought about by the setting free of the peroxide of chlorine; that is the gas produced, and it is probably the one that causes the polarization.

Mr. F. B. Crocker—About the polarization; it is very evident the active material there is $CL\ O_2$, and that is in solution in the liquid. There the oxygen of that $CL\ O_2$ combines with the carbon and sets free chlorine, and that chlorine is set free on the platinum, and that, of course, polarizes the cell; and I should imagine that Mr. Case's mechanical means for preventing the polarization are just the same as the mechanical means for depolarizing in a cell which polarizes by the liberation of gas on the negative plate, that is, simply shaking it, or roughening the surface, or using a platinized silver plate or anything of that sort, to get rid, more or less, of the gas, and in that way avoid polarization. There is also the formation of $C\ O_2$ (carbonic acid gas) on the positive plate. That also would produce polarization.

Mr. C. S. Bradley—The figures given seem to me hard to understand. (Referring to equations on the blackboard.) The heat units which are given out by the combination of different substances, of course, can be found in many books. In Watt's chemical dictionary, which I have here, will be found the heat of chemical combination and the heat of chemical action. The various energies are given and the number of heat units given out by an atom of the various substances. Now, we find, when we refer to carbon and oxygen, that 12 pounds of carbon uniting with oxygen to form carbonic acid, give out 94,800 heat units.

This will heat 94,800 pounds of water one degree. That is Andrews' determination. Favre and Silberman give 96,960. Now, in the first place it is necessary to reduce everything to a hydrogen basis. We find that there are two atoms of oxygen. This calls for four atoms of hydrogen. Therefore it is necessary to divide 96,960 by 4, giving 24,240. Now, the volt is about 23,030. I have tried it both experimentally and by calculation, and that is as near as I have been able to come to it. I presume that is not accurate. That, you see, would give a trifle over a volt. It is, perhaps, $\frac{11}{100}$ over a volt that that carbon is capable of giving theoretically. Now, that of course can be determined experimentally. There is also a way of calculating it from the foot-pounds and the correlation of forces, etc. Now, this is the measure of the chemical pressure—the heat units are the measure of the chemical pressure, and the chemical pressure determines the electrical pressure. You can get but just so many volts out of any combination of two substances, and you can calculate just the possible amount that you can get in volts.

The question of resistance is one of the main points in the whole of this subject. I tried, in 1882, quite a long series of experiments with fused salts and their action upon coal. Of course the oxygen of the atmosphere is absolutely necessary. We cannot by any means expect to accomplish direct conversion unless we use the oxygen of the atmosphere. Otherwise we must use a manufactured product, which must be very expensive. Therefore, we have got to introduce the oxygen of the atmosphere, which is just as essential as the coal. That battery costs a great deal more to run, from the chlorate of potash used, than a zinc battery. So that to get cheap power in that way it is necessary to use carbon or hydrogen, or the combination of those, or the oxygen of the atmosphere; and to use the oxygen of the atmosphere, you must either supply it at the time you are operating with the coal, or from the manufactured article. Manufactured articles are dear; so it is necessary to use it at the time. Therefore, I hit upon the plan of taking manganate of soda or potassium and putting a blast of air through the electrolyte, and by that means supplying it with air and allowing it to act on the coal, which is put into another part of the vessel. The main point is the resistance. The voltage falls very little short of the theoretical. That is all right; but the resistance is too high for it to be practical. At least I have always so regarded it. It would require a surface equal to a pond about ten feet in diameter per horse-power (laughter), that is, if you allow a space of two inches between the coal. Of course, coal is a rough substance. You have got to allow it a considerable distance between your plate on which the oxygen supply is furnished, and it is the coal which runs up the resistance.

Then, in studying up the matter, I saw in Watt's chemical dictionary that F. Braun had a determination of the conductivity of fused salts in the neighborhood of their melting points. Putting the conductivity of mercury equal to zero, he found that of the best sulphuric acid to be about 7,700. The following numbers were also obtained: Chloride of lead, 32,200; nitrate of soda, 11,475, and so on. But of all the records I have ever found, and in all the experiments I have tried, chloride of lead is of the lowest resistance or the highest conductivity among the salts. It is about four times as good as the best sulphuric acid. We noticed in some of the electrical papers of a late date mention of Mr. Acheson's device, in which he proposes to use gases in one case. Now, gases are of a great deal higher resistance than any fused electrolyte, and the fused electrolyte, of course, is, as I said before, too high. The lead chloride is the lowest. It is possible, of course, that somebody may find substances of very low resistance, but it is rather a hard job. Now, of course, I do not mean to advance this as a pessimistic view of the matter at all. It is just simply to make a statement of the conclusions which I have reached, which I hope may be of benefit to others, and perhaps save them some experiments and time.

Mr. Wetzler—The previous speaker, in criticising the apparatus devised by Mr. Acheson, in which gases are used as the medium between the electrodes, has remarked that they are of very high resistance. I think that is a question of relativeness merely. I do not know what the absolute resistance of the fused products which the previous speaker employed is, but we all remember the experiments originally made by Faraday, who, after placing the points of an electric circuit a short distance apart, heated up the terminals of the platinum wires and effected the passage of the current thereby. You also know that if we heat the air sufficiently, as is done in an electric arc, we get comparatively low resistance.

Mr. Bradley—I also made this experiment. I employed an outer vessel of zinc in which was placed a porous cup containing a bar of zinc. The outer vessel was filled with a concentrated solution of zinc chloride, and the porous cup was fed by a constant stream of fresh water to maintain the solution within it dilute. The vessel was then heated by a Bunsen burner from below.

In that way I could control it so as to keep the inner zinc cool, while the outside dish was heated. It is well known that chloride of zinc has a high heat of solution. My idea was, that if I could keep a strong solution in the outer vessel, just on the point of crystallizing, in contact with the zinc, and a weak solution within the porous cup, I could cause a passage of the molecules of zinc across and a current to be generated. The calculated electromotive force from the arrangement was $\frac{8}{10}$ of a volt. I worked at it a good while before I got $\frac{8}{10}$ of a volt, but finally I did get it. The question of resistance, of course, comes in, and that is the greatest difficulty in all apparatus of this kind. On weighing the outer vessel and the interior plate, the latter should have lost and the former should have gained. But I found that the inside one had lost; but it was hard work to find that the exterior one had gained anything. So it left me in doubt whether the $\frac{8}{10}$ volt was actually due to the heat of solution or not. But it is quite interesting as an experiment.

Mr. Crocker—The question of equi-volts is rather an interesting one. I shall not go into the figures, but I think Mr. Sprague, of England, has done the subject a good deal of harm by prefixing that "equi" to the well-known term "volt." People are used to that word, but the result of prefixing "equi" to it has been that people have let it alone, just as if he had attached a dynamite bomb to it. And really I do not see why it is put there. An equi-volt, as far as I can see, is just as much a volt as any other volt. It is well enough, perhaps, to designate volts obtained by chemical action as equi-volts; but I do not know any reason for it. You might just as well separate volts obtained by an Edison dynamo, and call them Edi-volts. Really these equi-volts are just plain, ordinary North American volts. And I think if that were used more—the calculation of the volt of chemical action—it would be of great service in a great many cases. For example, Mr. Bradley and I, before we had made any experiment at all on the subject, calculated out what would be the electromotive force of a combination of zinc and bromine; we calculated just as Mr. Bradley described there, by taking the heat units produced by the combination of zinc and bromine, and then going through those figures we obtained $1\frac{8}{10}$ volts. By a great many experiments, very carefully carried on, we got $1\frac{78}{100}$ volts. Now, that is just $\frac{2}{100}$ different from our calculations. At first we got $1\frac{8}{10}$, because, of course, the instrument would not detect that $\frac{2}{100}$ difference. It was only by continual experiments that we got the average of $1\frac{78}{100}$. Now, that is close enough for all practical purposes, and you can arrive at results which are practically close enough with a combination of zinc and iodine, for example, or any combination of two elements, or an element and a compound body. For instance, you can calculate out the electromotive force of zinc and chromic acid, or nitrate of soda, or any other depolarizer, and you will arrive at results which approximate quite close enough for practical purposes to the actual electromotive force obtained by experiment.

Now, that seems to me to be a very important thing, because very often you want to find out these facts and have not time to try it, and you save yourself the experiment by calculation; and, of course, all kinds of short cuts like that are often quite an advantage to the investigator, and, so far as I know, it is very seldom used. Mr. Sprague is about the only authority who speaks of it at all, and in practice I have never met any one who used that method. Some people doubt that you can get reliable results at all. They claim that they are mere accidental coincidences;

but I think when they occur a great many times and when you can actually prove by the figures that there is such a relation, then there can be no longer any doubt about it.

The contact theory has also prevented the adoption of this calculation of electromotive forces. The idea is that there is a contact difference of potential; that it is not due to the chemical action, but is due to the contact; that chemical action merely makes the action continuous. I never could see much in that contact theory myself. If you have a plain chemical affinity there, and that produces so much energy in the form of heat, for instance, why shouldn't it produce the same amount of energy in the form of electricity in a voltaic cell. The contact theory is one of those things that you cannot see any reason for. Why should zinc and bromine have a contact difference of potential of $1\frac{8}{10}$ volts? Whereas you *can* see a reason why they should have a certain chemical electromotive force. The contact theory is a purely arbitrary thing. A man tells you there is a contact difference of so-and-so. There is no reason for it that I can see, and the fact that the contact difference of potential is usually the same in liquids as in air, is due to the fact that there is oxygen, moisture, etc., present in the experiments, and you have substantially the same conditions that you have when you try them in a voltaic cell.

And those two theories of contact difference of potential and the "equi" prefix to "volt" have retarded a very important branch of science, I think.

Mr. Wolcott—I do not understand why the zinc would be dissolved off from one electrode and deposited on the other. Does the chloride of zinc dissolve the metallic zinc?

Mr. Bradley—The Grotthuss hypothesis is generally understood. There is a chain of molecules of chlorine and zinc all the way across the electrolyte. If there is more affinity for the zinc on one side than there is on the other, the zinc will cross over as soon as the current is closed.

ELECTRIC LIGHTING ON THE BOSTON AND ALBANY R. R.

Among the papers contributed to the International Railroad Congress, at Milan, was one by Mr. G. W. Blodgett, electrical engineer of the Boston & Albany railroad, from which the following data are taken relating to electric lighting by that company.

At East Boston the following points are lighted by electricity: First, the grain elevator, which has six lamps in a single line opposite the scales; 2d, freight-houses Nos. 6, 12 and 13 on the east; and freight-house No. 5, pier No. 1 and the entrance on the west, where ocean steamers load and discharge to the cars; 3d, a wharf where coal from vessels is discharged into cars; 4th, two engine buildings. There are also lamps in the yard near important switches and crossings. All these are Brush lamps of 2,000 nominal c. p. In the buildings they are 14 feet high, the greatest height which the buildings permitted. Out of doors the height is 24 feet. Although there are 48 lamps, only 36 can be operated at the same time. It is sometimes necessary to use a larger number of lights than can be operated by the dynamos. A choice is then made of those most indispensable, and the lighting is completed by gas or oil lamps furnished with reflectors.

Electric light is used only when the number of lamps needed is nearly the capacity of one dynamo; that is to say, 18. When only two or three are needed, gas is used.

The cost of the electric apparatus at East Boston, in place, was as follows: Buildings, $3,116.12; 60 h. p. engine, in place, $1,-737.10; shafting, pulleys, etc., in place, $364.29; belting, $412,30; two Brush No. 7 dynamos, $4,000; 44 lamps, with two sets of carbons, $3,520: two regulators for the dynamos, $250; wires, insulators, telegraph poles and cross-arms, and labor in setting up the machinery, lamps and wires, $1,322.75; total, $14,722.56. The boilers used for the elevator engine also supply steam for this, and the cost of boilers or boiler-house is therefore omitted. The cost of operation during the year ending Sept. 30th, 1886, was $2,277.34, or $7.28 per day, or 20 cents per lamp per day, assuming 36 are used. This includes fuel, but not cost of boilers or boiler-house. The lamps are used irregularly. When a vessel is at the wharf they are usually burned the whole night until the loading has been completed, when they are, perhaps, not used again until another vessel arrives, if it be delayed, unless the elevator is to run at night, or cars are to be unloaded. Two men are employed to run the engine and dynamos during the night and replace the carbons during the day. They work as many hours as is necessary—sometimes 20 hours or more in the day, when the lamps burn all night, and sometimes only four or five hours. The average is about 10 hours. When the electric lamps are not used, these men are employed in other work.

At Boston the passenger station, train house and yard are lighted by 33 arc and 12 incandescent lamps. There are two Brush dynamos of 16 lamps each, and as they are run at a speed of 825 turns per minute, 18 lamps can be used. They are placed at a height of 12 feet, except five, which are 24 feet high. Four men are employed; two renew carbons and make repairs during the day. Two others work at night: one for the boilers and engine, and another who operates the dynamos and patrols the circuits. The lamps have double carbons and can burn all night. They are lighted at dusk, and run until after the arrival or departure of the last train.

The cost of the apparatus, not including engine or boilers (which are in use by the repair shops), was as follows: Two Brush dynamos, $4,000; 33 double arc lamps, $2,640; 2 single arc lamps, $120; 2 automatic regulators for dynamos, $250; wires, insulators, fixtures, etc., and work of setting up, not including main shafting, etc., $1,206.47; total, $8,216.47. The cost of operation for the year ending Sept. 30th, 1886, was $6,-465 11, or $184.72 per lamp per year, or 50.6 cents per lamp per day. The cost per lamp hour was about six cents. The cost of power furnished is $2.50 per day, besides the wages of the engineer. Carbons cost 80 cents; oil waste, etc., about three cents per day. The cost of repairs to five Brush machines during six and one-half years has not been more than $150. Neither a lamp or dynamo has yet been replaced or sent to the factory for repairs. All such have been made by the men in charge. These installations were the first by a railroad company in New England, if not in America, and are still the most extensive. At Worcester the passenger station is well lighted by 20 arc lamps, placed 15 feet high in waiting rooms, and 24 feet in the train house. The cost is about twice as much as formerly paid for gas (which was never satisfactory), but several times the light is obtained. The cost is 70 cents per lamp per night. It costs about the same at Springfield. At Pittsfield the electric light company light the passenger station for the same price formerly paid for gas, about $1,400 per year.—*Railroad Gazette.*

DOMESTIC ILLUMINATION BY ACCUMULATORS.

The ball-room of Mr. Ogden Mills' residence, 69th street and Fifth avenue, was lighted by means of the N. Y. Isolated Accumulator Co.'s storage batteries on Monday night, 16th Jan. The occasion was a ball and house warming, and a large assemblage of the leading members of New York society were present. The ball-room was brilliantly illuminated by sixty 16 c. p. lamps—the electricity being supplied from the batteries which had been charged on the previous Friday at the Electrical Accumulator company's factory, Newark, N. J.; carted to Mr. Mills' residence on Saturday; placed in position in the cellar and connected with the lamps on Monday, and used from 9.30 P. M. until 3.30 A. M. the following morning without a single interruption of any kind.

The effect of the lights was very beautiful, and many expressions of admiration were heard on all sides.

Mr. Cornelius Vanderbilt afterward ordered sufficient storage batteries to illuminate his Fifth avenue mansion on the occasion of his grand ball given on the 23d Jan.

This is the first instance in which storage batteries have been used in America to furnish temporary light for special social occasions, and its success is likely to lead to a large business of this character in all prominent cities.

A DYNAMO WITH INTERNAL POLES.

Some time ago Messrs. Siemens & Halske, of this town, brought out a new type of dynamo with internal field magnets, which was described and illustrated in *Industries*, vol. iii., p. 45. A similar machine was also brought out by Messrs. Ganz & Co., of Buda-Pesth; but priority for the invention has been claimed by two other firms, viz., Messrs. C. & E. Fein, and the Helios Company, of Cologne, both of whom lodged protests at the Patent Office when Messrs. Siemens & Halske applied for a patent. From a recent decision of the Patentamt it appears that the protesting parties have been successful, and the following reasons are given for the refusal to grant the patent: "There have been prior publications, notably Patent No. 13,802, figures 12 and 13, covering the principle of internal magnets placed radially, and the manner of supporting the external armature laterally has also been anticipated in Patent No. 13,158, figure 2. Although these designs have previously been chiefly used for alternate current machines, it cannot be contended, with the present general knowledge of dynamo electricity, that the application of the design to continuous current machines is a patentable novelty. Moreover, such application has already been forestalled in Patent No. 19,265, figures 15 to 18." This decision will show how very strict the Patentamt is in dealing with inventions for which patents would be granted in England as a matter of course.—*Industries.*

THE TELEPHONE FIGHT AT ROCHESTER, N. Y.

A VICTORY FOR THE TELEPHONE COMPANY.

The subscribers to the Bell Telephone company's service whose contracts extended beyond Nov. 17, 1886, the date of Rochester's great telephone strike, are all interested in the test suit that was tried before Justice Rumsey, in the Circuit Court this week. The point at issue was whether the company could collect rents for instruments after the strike became general, and the subscribers whose contracts had not run out alleged that the service was

worth nothing to them, owing to the fact that so few people used the telephones as to reduce the number in active operation from 1,200 to about 200. This assertion was made by many of the strikers, notwithstanding that they themselves were refusing to answer the calls of their instruments as well as to send messages by them. Justice Rumsey to-day decided the point in favor of the Bell company, refusing to allow its suit against George H. Worrall & Co., to recover for back rent to go to the jury, but ordered a judgment of $66.87 for the company, which includes interest.

The amount of money involved in the suit is small, but as the suit was tried as a test case the issue is of the greatest importance. In directing a verdict Judge Rumsey said the contract into which the telephone company and the defendants had entered was decidedly one-sided, but with that feature of it he had nothing to do. Under that contract there was no guarantee that the number of subscribers would be increased or would not be diminished, or, in fact, kept up at all. It did not guarantee that the company would continue in business in the future except to complete its contracts. The company had just as full a right to close up its business as a grocer after completing its contracts. There was no evidence to show that the change from the flat rate to the toll system or that the prices under the toll plan were exorbitant or unreasonable. The only restriction in the most extreme view of the case that would be imposed on the company was that it could not willfully make such rates and conditions as would cause the public to be excluded from the right to use the system. Such an act must be of a willful character and for the purpose of exclusion. If the company raised the rates and if it were a mere error of judgment to the best means of conducting business that would be a mere mistake and would not constitute a willful act which could be restricted.—New York *World*, January 25.

ELECTRICITY AND THE LAW.

One of the new questions arising from the application of electricity for all the modern purposes in which it is now used, has been that of its relation to ponderable matter in the rights of property. There have been several instances in America where electricity has been diverted from leads of central stations by persons not subscribers, but abstracting it for their own use. Some time ago, we noted an account of the summary manner with which the proprietors of an incandescent light station in New York city treated the thieves of electricity, by sending for about a second over the line as heavy a current as the system would stand, thus ruining most of the apparatus of the thieves, and producing very mysterious electric phenomena, which formed the subject of a very learned paper read before one of the electrical societies. At Lowell, U. S., another man recently made connections with the wires for a telephone station not only for his own benefit, but also for that of some of his associates, with whom he had a central "station." The legal questions in the matter were of such a nature as to perplex even the very astute counsel of the telephone company. But there has recently appeared another problem in the matter. There is an electric light station in the town of St. Stevens, in the Province of New Brunswick, the conductors of which lead over the St. John's river to Calais, U. S., and the collector of customs on the part of the United States, vigilantly watchful of its position in the enforcement of a protective tariff, immediately sent to the secretary of the treasury of the United States to ascertain what would be the duty on electricity, and it has finally been decided by the official head that electricity is not dutiable, being an invisible and subtle agent of power, possessing no substance as a merchantable commodity. The question as to whether the bees who

"Gather honey all the day,
From ev'ry opening flower,"

in Mexico, and then flew to their hives in Texas, did not commit smuggling, or, at least, were dutiable in themselves, was not considered a clear precedent in the above ruling of the secretary of the treasury.—*Engineering* (London).

TELEPHONE PATENTS IN MEXICO.

The Supreme Court of Mexico, by decision published January 19th, has sustained the validity of the Bell and Blake patents, which in this country are held by the Mexican Telephone Co. The suit did not arise from any question as to the claims of Bell and Blake, but grew out of an action for infringement of patent brought by the telephone company against parties who had sold instruments not supplied by the company. Defendants took the ground that although patents had been granted to the telephone company by consent of Bell and Blake, the former was not legally entitled to hold them, as the laws of Mexico require that patents should be issued to actual inventors and that assignments should be made afterwards. This suit has been followed with much interest, and to-day's decision, which confirms the title of the Mexican Telephone Co., is considered of great importance. —New York *World*.

OBITUARY.

Balfour Stewart.

Professor Balfour Stewart, M.A., LL.D., F. R. S., died on Monday, December 19, at Ballymagarvey, Ireland, having just completed his 59th year. He was educated at the Universities of St. Andrews and Edinburgh. In 1859, he was appointed to the directorship of the Kew Observatory, and in 1867, to the secretaryship of the Meteorological Committee, which last appointment he resigned on his promotion to the Professor's chair of Natural Philosophy in Owen's College, Manchester, in the year 1870, a position which he held until his death. Two years before this distinction was conferred upon him he had been awarded the Rumford medal by the Royal Society for his discovery of the law of equality between the absorptive and radiative powers of bodies. Together with Messrs. De la Rue and Loewy, he wrote "Researches on Solar Physics," and he and Professor Tait published their researches on "Heating produced by Rotation in Vacuo." Besides these he wrote a number of treatises especially on the subjects of meteorology and magnetism. The article in the *Encyclopædia Britannica*, on "Terrestrial Magnetism" is from Professor Balfour Stewart's pen. Among the many works of which he was sole or joint author may be mentioned the "Elementary Treatise on Heat," "Lessons in Elementary Physics" (1871), "Physics" (1872), "The Conservation of Energy" (1874), and "Practical Physics" (1885). Most of these are text-books on the subjects of which they treat. He and Professor Tait also produced the "Unseen Universe," a work of which 12 editions have been published. At the time of his death he was President of the Physical Society, and was a member of the committee appointed to advise the Government on solar physics. We reprint elsewhere from the columns of *Nature*, a more extended account of Professor Stewart's life and works, by his friend and associate Professor Tait.

Franz Carl Guilleaume.

The head of the noted firm of Felten & Guilleaume, of Mülheim on the Rhine, who died on the 1st of December last, from the consequences of an operation, was a manufacturer and an organizer of business of a high order. He was born on the 30th December, 1834, at Cologne, and was a grandson of Franz Carl Guilleaume, who in conjunction with his father-in-law, Theodor Felten, had established the firm of Felten & Guilleaume, in the year 1824.

The deceased assumed sole proprietorship of the firm in the year 1865. His energy, spirit of enterprise and skillful management achieved for the firm a well merited celebrity throughout the business world. The firm's original business was the manufacture of rope and cordage, at Cologne, to which was ultimately added wire, wire ropes and telegraph cables, and the works were removed to Mülheim.

The late F. C. Guilleaume was ever anxious for the welfare of the 2,500 hands and numerous officials in his employ, and has left behind him many providential institutions which will serve to keep his remembrance fresh in their minds. We may mention for instance the numerous dwellings erected for his officials and workmen, and which are exemplary from a sanitary point of view; the co-operative stores with savings bank; an institution for the care of young children during the working hours of their parents; a beneficary fund for deserving employees, unfortunate or disabled, and other similar provisions.

Mr. Guilleaume possessed not only an acute and disciplined mind, capable of devising and executing large enterprises, but, we are happy to say, an enlightened human sympathy, and directed much of his effort to the well being of the large number of persons drawn about him by his large undertakings.

ELECTRIC STREET RAILWAYS IN AMERICA.

Now in Operation.

ABBREVIATIONS.—**mi.**, miles of single track; **g.**, gauge; **lb.**, pounds rai per yard; **m.**, electric motors; **c.**, cars; **m. c.**, motor-cars; **h. p.**, horse-power; **T.**, T-rail. Name of electric system used is in SMALL CAPITALS.

Notes.

FROM statements recently published it appears that the Edison electric cars, operated by accumulators, have run a total distance of over 30,000 miles in London, since August 1, 1887, and that the service has been performed in the most perfect and practical manner. The number of passengers carried per trip shows a marked increase, which is good evidence of the popularity of the system with the traveling public.

WM. WHARTON, JR., of Philadelphia, publishes in the *Electrical World* a challenge to electrician C. O. Mailloux, of the Julien Electric Company of New York, offering to pay all expenses if the latter will bring a Julien electric street car, and make three runs in competition with the Reckenzaun car. Mr. Wharton says: "For every mile that his car makes more than our Reckenzaun car I will pay $100, provided that he pays $50 for each mile that his car makes less than our Reckenzaun car, the money to go to some charitable organization." George B. Prescott, Jr., whose opinion on electric car work is entitled to great weight, makes the very pertinent comment, that in view of the entire absence of any useful data such a test would prove nothing at all, or as he puts it: "To claim that an unknown charge of an unknown battery will propel an unknown car twice as many miles as another unknown battery will propel another unknown car is about as instructive as to say that a locomotive can go further than a horse." Mr. Mailloux has not yet, so far as we have observed, responded to the challenge.

THE JULIEN ELECTRIC TRACTION CO. has been incorporated in New York by William Bracken, L. Willoughby and Edward O. Coles, with a capital of $3,000,000, for the manufacture of electrical appliances and electric railway machinery.

A CORRESPONDENT of the *Electrical World* recommends slate as a great improvement over fibre, mica and other materials ordinarily used, for insulating the brush-clamps of dynamo machines.

PERSONAL MENTION.

Messrs. Wiedersheim and Kintner, of New York and Philadelphia, solicitors of patents and experts in electrical cases, have associated with themselves Mr. Carl Hering, of Philadelphia, as consulting electrician. This is a very well advised step on the part of Messrs. Wiedersheim and Kintner, as Mr. Hering's knowledge and experience of electro-technics will undoubtedly prove of great value in such investigations as are frequently required in the study of inventions or technical questions arising in litigation.

"Dr. Otto A. Moses," says the *Electrical Review* of January 28th, "is still absent in Europe. An electric light convention without the presence of the versatile doctor will not seem at all natural." Our valued contemporary will be glad to be corrected, and to learn that Dr. Moses returned to New York, January 24th, and that his genial presence may fairly be expected at the Pittsburgh meeting.

ELECTRIC LIGHT AND POWER.

THE UNITED STATES ELECTRIC LIGHT CO. has completed its new lamp factory in Newark, N. J., fronting 135 feet on Orange street and 125 feet on Plane street. It is four stories high, and has a 12 foot basement, which is used for the heavy machinery, engines, dynamos, air pumps, etc., for exhausting, and force pumps for the glass-workers employed in sealing the lamps. The laboratory is on the first floor and is fitted out with a complete line of test instruments, some of the most delicate of which are made by the company's own experts. The upper floors of the building are devoted to exhausting, testing and finishing the lamps. The elevators, stairways, wires, etc., are all in separate compartments outside the building. The company is at present about 100,000 lamps and 120 machines behind its orders. In New York city it has recently been engaged fitting out the Metropolitan Life building in Park place and the American Tract Society's building, at the corner of Nassau and Spruce streets, besides large extensions of the plant in the Equitable building. The Philadelphia post-office takes 2,500 lamps. The Troy Electric Light Co. makes a large increase, as do also the Rochester and Newark companies, and altogether about a score of new stations have been started in the last three months.

THE CERTIFICATE of increase of the capital stock of the Zanesville Electric Light Co. from $25,000 to $75,000 has been filed with the secretary of state. Secretary Durban says that this action was taken at the annual meeting in December, although the electric light plant had been increased to that valuation some time before.

HYDE PARK, which is a suburb of Boston, has a population of about 9,000. It is a manufacturing town as well as a place of residence for people doing business in the city. For the past two years the question of lighting the streets by electricity has been agitated, and six months ago the town decided to adopt that form of illumination. The contest for lighting the town was principally between the American and the Thomson-Houston companies. After the appointment of committees and a most thorough examination of both systems, the American was finally adopted by the selectmen, and a contract made with the American Electric Manufacturing Co., of New York, to light the streets with 75 arc lights. The company put in a 100-light plant, and it is said that the installation is one of the finest in Massachusetts. The lights were started on the 14th of January, and according to the local paper, the Norfolk County *Gazette*, the people were jubilant over the occasion. It is said that the town will need 100 lights, and that the mills and stores in the town will use the light to a considerable extent, so that it is safe to say that it will not be long before the present number of lights in the town will be doubled.

THE GAS AND ELECTRIC LIGHT COMBINATION is making satisfactory progress in New England. One of the most recent converts to this system of mixed lighting is the Pawtucket Gas Co., of Pawtucket, R. I., the general manager of which, Mr. Stiness, is

laying out to do a large amount of electric lighting in connection with his gas industry. He is building one of the finest stations in New England, and has adopted the American system, which is now being installed.

A COMMITTEE of the Board of Aldermen of Detroit, Mich., has been appointed to investigate the practicability of the city owning and operating its public electric lighting plant, and for the purpose of obtaining all possible information upon the different systems.

THE MILLS and factories in various sections of New England are going into the electric lighting to a great extent, and the American system, judging by the number of new installations and the satisfaction expressed by the users of the light, is in high favor with them. The Arlington Mills, of Lawrence, Mass., are now using about 450 lights, and it is said the management is contemplating a large addition to the present plant.

Foreign.

Belgium.—The Thomson-Houston Co. has bought some ground at Brussels, in the Champ de Mars, for the installation of steam engines and dynamos for lighting the Théâtre Molière. This company has also arranged with M. Meunig to light in the district of Ixelles, in which the theatre is situated, the Porte de Namur, the Théâtre Café, and part of the Chaussée de Wavre. A proposal has also been made to the local authorities to light the whole quarter electrically instead of by gas, but the offer has not been accepted. Electric lighting is making rapid headway, especially in Brussels, and among those who have lately adopted it are several cafés in the centre of the town, and the Foire de Leipzig emporiums. A syndicate is spoken of to promote the adoption of electric lighting, which will include Messrs. Mourlon, Gérard, & Co., and the Société Industrielle d'Electricité.

England.—ELECTRIC LIGHTING IN LONDON.—Mr. W. Lant-Carpenter delivered an interesting lecture to the members of the County of Middlesex Natural History and Scientific Society on Tuesday evening, at the rooms of the Medical Society of London, in Chandos street, Cavendish square. His subject was: "The Position and Prospects of Electric Lighting in the Metropolis," which he treated in the manner most calculated to commend it to the attention and intelligent interest of his audience; that is to say, the lecture was a "popular" one to a certain extent, but contained a vast amount of information likely to be useful to those of his hearers who may have it in contemplation to make use of the electric light for themselves. The portions of his lecture in which we were most interested were those in which he treated of the "prospects" of the light in London; with its "position" we were necessarily already more or less familiar. A few of the points elicited by Mr. Carpenter from the various companies and lighting firms will be of interest to our readers. The Maxim-Weston Co., he gathered, has almost completed a large installation at the establishment of Messrs. Crisp, in the Seven Sisters Road, where from 40 to 50 arcs, and 300 or 400 incandescent lamps are to be employed. Overtures have been made to the same company for the erection of a central station in the city to light 5,000 lamps. The firm with whom the company is in communication guarantee to take 1,000 lights themselves for three years, and to find customers for the remaining 4,000 lights. Again, certain private individuals have subscribed a large sum to provide for an installation of 1,000 lights in another part of the city. This looks like a promise of great activity in the city during the present year. Further west, Mr. J. E. H. Gordon is putting up an installation of 5,000 lamps for the lighting of a huge building near Whitehall and the National Liberal Club. The E. P. S. company has upwards of 3,500 lamps running from its accumulators in the city, and anticipate a large increase. Messrs. Crompton & Co., have applied for powers to considerably extend the Kensington Court installation, embracing nearly the whole of Kensington, Knightsbridge, Brompton, and a portion of Chelsea, probably the richest part of residential London. Mr. Carpenter visited the Kensington Court station, and was impressed by the compactness of the plant. There are at present 1,000 lamps running, and 500 more are contracted for, all in private houses; there is room at the station for the triplication of the plant and the provision of current for 20,000 lamps. The house furthest removed from the station is at a distance of 900 yards, but Mr. Crompton is confident of his ability to carry current to distances of two or two and a half miles. Current is also supplied for small power motors and for arc lights. The charge imposed is 8d. per Board of Trade unit, or 0.28d. per hour per lamp, amounting to about double the price of gas. The shares in the company which owns this installation are at 50 per cent. premium, a fact which speaks well for the confidence of the shareholders in its success.—*The Electrical Review* (London.)

Germany.—The experiment recently made in Berlin of joining the underground mains of two central stations has proved completely successful. Hitherto the network belonging to each station has been kept distinct from neighboring mains, but as such a subdivision entailed greater administrative expenses and a greater outlay for reserve machinery, the Allgemeine Elektricitäts Gesellschaft resolved to join their two stations, one in the Markgrafenstrasse and the other in the Mauerstrasse, so that during the day time and late at night only one of these stations need be kept at work.

The electric light installation in what is known as the German Theatre, in Berlin, has now been completed down to the smallest rooms. The lamps employed were made by the new company manufacturing the Seel glow lamp. The following is a list of the lamps installed:

Five flies, each three rows of forty lamps, in three colors—red, green and white	600
Two front wings, each twelve lights	24
Flies over the back of the stage	45
Foot lights	42
Auditorium	106
Foyer	200
Cloak and store rooms	150
Stairs and corridors	150
Vestibule, bar and box office	150
Offices	18
Total	1485

On each side of the stage there are five plugs for the attachment of incandescent light cables, and two for arc lights. The latter have separate resistances, whilst the glow lights are regulated by a stage rheostat in groups. The Seel lamps, so far, have stood very well: they can be worked at a high temperature without the risk of breaking, and do not appear to blacken the glass bulbs so much as other forms of incandescent lamps. The manager of the theatre considers the working expenses with the electric light smaller than with gas lights; but in his calculation no allowance has been made for interest on the cost of plant.—*Industries.*

According to *Industries*, an electric locomotive has been built in Berlin, and public trials are announced to take place on a tram line. The motor is in design similar to a Gülcher dynamo, is speeded at 300 revolutions, and connected with the axles by spur gearing. Electric power is supplied by a battery of E. P. S. accumulators, giving 200 volts and a maximum rate of discharge of 40 amperes. The total storage capacity is 300 ampere-hours, and the estimated speed is 7½ miles per hour.

Recent official statistics give the whole number of electric lamps in Germany as 15,000 arc and 170,000 incandescent, operated by a total number of 4,000 dynamos. The total estimated horse-power is about 30,000 (indicated). One firm in Berlin makes 2,000 incandescent lamps per day.

Spain.—In the matter of electrically lighting the Royal Theatre at Madrid, Mr. Edward P. Thompson, of New York, is consulting electrician, under appointment of the Consul General of Spain.

THE TELEPHONE ON THE ALPS.

Telephonic apparatus has been installed with great success in the Hospice of the Great St. Bernard. We may accordingly expect one of these days to see the regions of thick-ribbed ice gleaming under electric beams, as we may already see Bengal lights thrown on the cascades and glaciers of the great Alps. The occupations of the mastiffs who hunt up lost travelers will be gone, and the cowl-clad canon who acts as the benevolent and affable prior of the monastery will be replaced by a ruddy and rubicund Boniface, to whom tourists will telephone for beds. The installation of the telephone amid the sempiternal snows suggests many more peculiar possibilities; but for the present the instrument will be used for a definite and very laudable purpose. The facts of the case are these: Canon Bourgeois, Prior of the Great St. Bernard, took it into his learned head about 12 months ago, that, if telephone offices were organized at St. Remy, in the monastery itself, and at Proz en Valais, the number of fatal accidents annually happening among French and Italian workmen while crossing the mountains between October and May might be diminished. He communicated the idea to Canon Bérard, of Aosta, who took up the matter with energy. M. Bourgeois had invented a telephonic apparatus of his own, and after a while the Swiss and Italian governments gave their respective sanctions to the proposed plans. The Prior was duly authorized to join his telephone to the telegraph wire between Aosta and Martigny. Since then telephones have been in operation at La Thuile, in the Hospice of the Little St. Bernard, and in several of the adjacent cantons. Last Sunday the Canon had a kind of field day with his telephones, and, making the Little St. Bernard his temporary headquarters, he conversed with the brother in charge of the office in the Hospice of the Great St. Bernard, and with the officials in the various cantons.—*Electrical Review* (N. Y.).

NEW INCORPORATIONS.

The Great Falls Electric and Power Co., of Great Falls, Md. Capital stock, $200,000. E. J. Ellis, and others, incorporators.

The Seward Electric Light and Power Co., Seward, Neb. Capital stock, $10,000. John Cattle, and others, incorporators.

The Berkley Electric Light Co., Berkley, Cal. Capital stock, $30.000. R. P. Thomas, and others, incorporators.

The Napa Electric Light Co., Napa City, Cal. Capital stock, $50,000. George L. Henzel, and others, incorporators.

The Hauss Electric Manufacturing Co , Cincinnati, O. Capital stock, $250,000. David J. Hauss, and others, incorporators.

The Seneca Electric Light Co., Seneca Falls, N. Y. Capital stock, $60,000. Simeon L. Phillips, and others, incorporators.

The Mahanoy City Light, Heat and Power Co., Mahanoy City, Pa. Capital stock, $15,000. W. L. Yoder, and others, incorporators.

The Conshohocken Electric Light and Power Co., Conshohocken, Pa. Capital stock, $20,000. T. H. Seeble, and others, incorporators.

The Union City Electric Light, Gas and Water Works Co., Strong City, Kas. Capital stock, $10,000. W. P. Martin, and others, incorporators.

The Rutland Electric Co., Rutland, Vt., have increased its capital stock by $25,000, and will make extensive improvements to its plant.

The Piscataquis Woolen Co. contemplate the establishment of an electric light plant at their mill at Guilford, Me.

C. H. Dexter & Sons will erect an electric light plant at their mills at Windsor Locks, Conn.

The Citizens' Electric Light Co., New Albany, Ind., will erect a plant.

The Buffalo Illuminating Co., Buffalo, N. Y. Capital stock, $100,000. Daniel E. Bailey, and others, incorporators.

The Roodhouse Electric and Power Co., Roodhouse, Ill. Capital stock, $5,000. Ellis Briggs, and others, incorporators.

The Presque Isle Electric Light Co., Presque Isle, Me. Capital stock, $10,000. James W. Bolton, and others, incorporators.

The Weston Electric Light Co , St. Louis, Mo. Capital stock, $60,000. F. L. Johnson, and others, incorporators.

MANUFACTURING AND TRADE NOTES.

ALFRED F. MOORE, successor to Jos. Moore & Sons, manufacturer of insulated wire for all electrical purposes, Philadelphia, announces that Mr. Chas. C. King and Mr. Antoine Bournonville have been admitted to an interest in the profits of his business, the firm name remaining as heretofore.

THE POPE MFG. Co., of Boston, have issued a novel business calendar and stand for 1888, of special interest to wheelmen. It is called the Columbia Bicycle Calendar. In this calendar a new departure has been made. The calendar proper is in the form of a pad, containing 366 leaves, one for each day in the year, to be torn off daily. The pad rests upon a portable stand, and when placed upon the desk or writing table the entire surface of the date leaf is brought directly, and left constantly, before the eye, furnishing date and memoranda, impossible to be overlooked. Upon each slip appear fresh quotations pertaining to cycling from leading publications and prominent writers—a collection which illustrates the popularity and universality of cycling the world over.

THE GLOBE ELECTRIC Co., Cleveland, Ohio, manufacturers, importers, and dealers in electrical apparatus and appliances, issue a circular describing a number of novel and convenient sets of domestic apparatus, as call-bells, annunciators, etc. They make a specialty of this class of work.

MESSRS. CHAS. A. SCHIEREN & Co., report sales of leather link belting to the following concerns for use on dynamos. Plainfield Electric Light Co., Plainfield, N. J., 46 feet, 14" standard link belt. Edison Electric Ill. Co., New Orleans, La., 43 feet, 10" standard link belt—53 feet, 10" standard link belt. Peoples' Electric Light Co., Trenton, N. J., 42 feet, 10" standard link belt. Pennsylvania Pulp and Paper Co., Lock Haven, Pa., 30 feet, 6" standard link belt. Edison Machine Works, Schenectady, N. Y., 44 feet, 8" standard link belt.

THE SHULTZ BELTING COMPANY, of St. Louis, a prominent local industry, had an opportunity to display remarkable enterprise a few days ago. It came when the Brush electric light plant was burned out, completely destroying all the belting of that extensive establishment. The consequence was that darkness hung over the stores of the company's patrons, and they began calling for electricity. There was no way of producing a current without belting, and as the sizes wanted were of such unusual dimensions none could be found in stock. Therefore, the Shultz Belting Company began that afternoon to manufacture belting from the leather which they had on hand. By working their forces night and day they succeeded in having the Brush plant in full operation again at 3 o'clock Monday afternoon. In the meantime, five double 12-inch, one double 20-inch, one double 24-inch, 210 feet of 12-inch, 72 feet of 20-inch and 72 feet of 24-inch leather belting was cut, made and fitted accurately to the electric pulleys. This is thought to be the quickest job ever accomplished in this line of manufacture, and is fully in keeping with the enterprise of the firm, which is second to none in the country.

THE SHAVER CORPORATION, 157 Broadway, New York, manufacture and supply Mr. Shaver's Mechanical Telephones. Mr. Shaver has given much attention to making serviceable telephones for short distances on the mechanical principle of the old "lovers' telegraph." Such telephones render excellent service on short lines properly constructed. There is evidently a very considerable field for their introduction.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions*, 11 *Wall Street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From Dec. 20th, 1887, to Jan. 17, 1888 (inclusive).

Alarms and Signals:—*Signal-Box*, M. Martin, 375,063, Dec. 20. *Hotel Signal*, H. B. Cox, 375,442. *Automatic Cut-Out for Fire-Alarm Box Controllers*, C. D. Rogers, 375,569. *Electric Call-Box*, L. B. Firman, 375,617. *Fire-Extinguisher and Alarm*, C. E. Kells, Jr., 375,636, Dec. 27. *Fire Alarm Circuit*, J. P. Barrett, 376,133. *Receiving, Transmitting and Distributing Instrument for Electro-Magnetic Thermoscopes*, H. J. Haight, 376,149. *Annunciator*, J. P. Tirrell, 376,171, Jan. 10.

Conductors, Insulators, Supports and Systems:—*Clip or Hanger-Clasp for Supporting Cables, &c.*, T. T. Eckert, 374,948. *Insulator*, E. C. Emery, 375,276. *Insulated Electrical Conductor*, A. Kissell, 375,295, Dec. 20. *Underground Electric Conductor*, DeW. C. James, 375,633. *Flexible Standard and Conductor for Electric Lights*, E. C. Fasoldt, 375,702, Dec. 27. *Conduit for Electric Conductors and Power Cables*, I. LaR. Johnson, 375,876. *Covered or Insulated Wire or Conductor*, L. F. Requa, 375,952, Jan. 3. *Pole-Indicator for Electric Conductors*, A. Berghausen, 376,281, Jan 10. *Electric Conduit*, R. Van Buren and J. J. Powers, 376,562, Jan. 17.

Distribution:—*Cut-Out for Electrical Distribution Apparatus*, M. M. M. Slattery, 375,014, Dec. 20.

Dynamos and Motors:—*Dynamo-Electric Machines*, J. Gray, 374,959. *Combined Electric Motor and Fan*, H. H. Blades, 375,255, Dec. 20. *Electrical Converter, Motor and Generator*, R. Eickemeyer, 375,542. *Electric Motor*, J. F. McLaughlin, 375,560. *Electric Motor*, E. Julien, 375,676, Dec. 27. *Armature for Magneto-Electric Machines*, W. Humans, 375,750. *Magneto-Electric Machine*, same, 375,751. *Regulating Alternate Current Electric Generators*, K. Zipernowsky and M. Deri, 375,910, Jan. 3. *Dynamo-Electric Machine or Motor*, E. Thomson, 376,120. *Dynamo-Electric Machine*, F. Jehl, 376,307. *Armature for Dynamo-Electric Machines*, H. Lemp, 376,326, Jan. 10.

Galvanic Batteries:—*Galvanic Battery*, J. Serson, 375,007. *Carbon Electrode for Galvanic Batteries*, C. H. Wilder, 375,034, Dec. 20. *Galvanic Battery*, H. B. Cox, 375,441; J. F. McLaughlin, 375,559. *Primary Electric Battery*, same, 375,561, Dec. 27. *Battery Zinc*, J. Beattie, Jr., 376,228, Jan. 10.

Ignition:—*Electric Gas-Lighting Apparatus*, C. B. Bosworth, 375,118, Dec. 20. *System of Electric Gas-Lighting*, W. H. Doering, 375,414. *Sparker-Coil for Gas-Lighting*, R. Eickemeyer, 375,614, Dec. 27.

Lamps and Appurtenances:—*Combined Gas and Electric Light Fixtures*, S. Bergmann, 375,117, Dec. 20. *Supporting Arm for Electric Lights* D. B. Banks and G. K. Hutchins, 375,977. *Electric Arc Lamp*, W. H. Miller, 376,-007, Jan. 3. *Lighting Cars by Electricity*, A. D. Stevens, 376,116. *Electric Lamp*, L. H. Leber, 376,323, Jan. 10. *Combined Incandescent Electric-Lamp Socket and Electrical Converter*, E. A. Colby, 376,583. *Combined Gas and Electric Light Fixture*, S. B. H. Vance, 376,617, Jan. 17.

Measurement:—*Electric Meter*, W. A. Stern, 375,392, Dec. 27.

Medical and Surgical:—*Electric Exercising Machine*, E. W. Robinson, C. H. O'Brien, and H. M. Breen, 375,835. *Electric Therapeutic Device*, E. R. Whitney, 376,018, Jan. 3.

Miscellaneous:—*Electro-Pneumatic Mechanical Movement*, H. L. Roosevelt, dec'd, 375,001. *Method of Electric Welding*, E. Thomson, 375,022. *Electrical Circuit Closer*, M. M. Welch, 375,238. *Thermo-Electric Generator*, E. G. Acheson, 375,242 and 375,243, Dec. 20. *Commutator or Electric Circuit-Breaker*, C. D. Baker, 375,328. *Electrically Propelled Vehicle*, S. D. Field, 375,346. *Portable Electric Coal Mining Machine*, J. B. Sneathen, A. Michaels and M. A. Michales, 375,390. *Calelectric Generator*, E. G. Acheson, 375,408. *Electrical Cut-Out Device*, J. C. Chamberlain, 375,476. *Electric-Circuit Changing and Signaling Apparatus*, I. H. Farnham, 375,543. *Electro-Magnetic Arresting and Releasing Mechanism*, same, 375,544. *Tension Device for Winding Electro-Magnets*, J. W. Easton, 375,697, Dec. 27. *Electrical Synchronous Movement*, H. C. Bridger, 375,727. *Permanent Magnet for Electrical Apparatus*, W. Humaus, 375,749. *Lightning Rod*, S. R. Lawshe, 375,756. *Apparatus for Electric Welding*, E. Thomson, 375,784. *Backing Electrotype Shells*, J. R Cummings, 375,869. *Electrical Heater*, J. P. Barrett and J. F. Mehren, 375,915. *Mold for Forming Pieces of Carbon for Electric Purposes*, C. H. Wilder, 376,019, Jan. 3. *Electric Circuit-Breaker*, W. R. Cole, 376,071 and 376,072. *Electric Lock*, C. A. Tucker, 376,-121. *Method of, and Apparatus for Producing Animated Pictures of Natural Scenery and Life*, A. LePrince, 376,247, Jan. 10. *Mechanism for Electrically Controlling Stamping Machines, etc.*, O. Mergenthaler, 376,541. *Electro-Magnetic Device*, C. E. Brush, 376,630. *Automatic Electric Valve*, C. EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 115 *Nassau Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions o, subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. VII. NEW YORK, MARCH, 1888. No. 75.

SPECIAL NOTICE.—To afford an opportunity to become acquainted with **THE ELECTRICAL ENGINEER**, *the publishers will send it to any new address for* THREE MONTHS *for* FIFTY CENTS.

"SYSTEMS."

THAT the author of the valuable contribution to electrical literature, known as "Primer No. 0," was a profound student of the tendencies of modern electrical arts, is sufficiently evinced by his sapient remark that "dynamos may be painted of various colors without increasing their efficiency." The same result which was aimed at in 1884, by means of chromatic effulgence, is in these later days sought to be attained by the more or less ingenious application of the much abused word "system." This process has perhaps reached its highest development in connection with electric railway inventions. For example, let us start with the assumption that there are, say, four ways of supplying electricity to a motor on a moving vehicle, viz:—by an overhead wire, a supplementary conducting rail, an underground conduit, and a storage battery. These, let us say, constitute the respective systems of Smith, Brown, Jones, and Robinson. Now, John Doe, by substituting his own form of motor for that of Smith, in the first named organization, produces the "Doe system;" or if he is mentally unequal to the task of devising a motor of his own, or even of purchasing one in open market and repainting it, he can at least take the motor of either Smith, Brown, Jones, or Robinson, and substitute it in some one of the other systems, which will answer every purpose. This gives him a choice of twelve different combinations, besides the four with his own motor, and it would indeed be a pity, if having sixteen different combinations to choose from, the "Doe system" should not be a pretty good thing. Richard Roe, on the other hand, takes Robinson's motor and storage battery, and substitutes an alloy of somewhat different proportions in the battery plates, and behold! "Richard Roe's system of electric traction." Occasionally, however, the claims of these rival inventors clash with each other and give rise to hard feelings, and much-to-be regretted recriminations. For instance, Jobson and Dobson invent a "system" by combining Smith's conductor with Jones's motor, contemporaneously with the invention by Hobson and Wobson of another "system" due to the combination of Smith's motor with Jones's conductor. Thereupon the advertising, business notices, and correspondence columns of the trade journals resound with the clamors and contentions of Dobson, Hobson, Jobson and Wobson, and of their general agents, local agents, and advertising agents, until everybody is tired.

Of course all this is a great pity, but as it is wholly due to the "system," there is no apparent remedy. In the case of the ordinary every-day street railway, if any one should publicly announce that he had invented a new "system" of street railway traction, which consisted in the use of mares or of mules, public ridicule would speedily put an end to his pretensions. But electricity is a mysterious agent. Nobody knows whether it is a fluid, or a force, or a mode of motion, and, therefore, it is only necessary for the originators of new electrical "systems" to discourse learnedly of "fundamental patents," "coefficients of mutual induction," and of "magnetic saturation," and the like, to convince the public that they have really got hold of something very extraordinary.

Seriously, if this silly affectation of calling every trifling modification of a well-known organization a new "system" is carried much further, the electricians of America will be in no small danger of rendering themselves the laughing stock of the world.

THE ELECTRIC LIGHT CONVENTION AT PITTSBURGH.

THE last meeting of the National Electric Light Association was in all respects interesting and important. We devote the greater part of our present enlarged number to the papers read at the meeting, and the discussions and proceedings of the Convention. The twelve papers read and discussed were all upon topics of practical and immediate interest to the art and business which underlie the association and give it its name. Much light was thrown upon questions relating to the employment of new methods, both electrical and mechanical. Distribution by alternating currents and converters formed a leading topic of consideration, while underground wires received scarcely less attention; both subjects were ably presented in papers read and discussed. Electric motors were treated theoretically on the electrical side, and practically on the business side. The proper adaptation of steam power plant to electrical distribution, improvements in leather belting, and the automatic recording of steam pressure, were among the mechanical subjects of papers and discussion. Other topics, closely allied to electric lighting, were the protec-

tion of watches from magnetization, and the relation of electric lighting to fire insurance. The full text of all of the papers will be found in our present issue.

The action of the Association in raising the annual membership fee to $20, and in employing a permanent Secretary seems very judicious, and should tend to increase largely the usefulness of the organization.

In treating the question of reform in the patent system, both the committee on that subject and the Association have wisely recognized the danger of attempting a general revision by a commission, as at first proposed, and confined their action to approving an effort for two specific changes—an increase in the salary of the Commissioner of Patents, and the creation of an Appellate Patent Court.

ELECTRIC RAILWAYS FOR CITY TRAFFIC.

The results of the operation of street-railway cars by accumulators, while thus far not in all respects entirely satisfactory, have been at least sufficient to place it beyond question that the cost of this mode of traction is somewhat less, probably materially less, than that of animal power. At least four independent sets of experiments under different conditions, have been carried on during the past year, in Boston, New York, Jersey City and Philadelphia, and a general review of the results shows that the accumulator itself has proved equal to the requirements of the service. Of course it would be desirable if the ratio of yield of power to the weight and cost of the accumulator could be increased, as it doubtless will be; but even if this expectation should not be fulfilled, we are fully satisfied that the work can be done, and done with entire satisfaction by means of the accumulators now on the market. The principal need for improvement now lies in the adaptation of the motor to the conditions of electric supply on the one hand, and to the requirements of the running gear of the car on the other hand. Great improvements in both these respects have been made within a few months, and it seems certain that the coming season will see the problem successfully solved, possibly in more ways than one.

It is gratifying to learn that the conduit system of electric distribution, which has quite recently been put into actual service in a city street, is thus far giving excellent satisfaction. If this method of supplying the electric current to the cars prove to justify the expectations of its friends, it is not too much to say that every dollar hereafter invested in cable systems for lines of level and moderate grades, in our large cities, will be absolutely thrown away. In all probability, the present year will see the question settled beyond a peradventure.

DISASTROUS ECONOMY.

In a recent article, we had occasion to comment upon the deterioration in the quality of the telegraphic service which has become so apparent in recent years, which in our opinion may be traced in a large measure to the growing practice of entrusting important business to the hands of immature boys and girls. Many of these young operators are not only deficient in judgment, but are quite innocent of any adequate sense of responsibility. The truth of our remarks has almost immediately received an unexpected and startling confirmation in the shape of the statistical table of railway accidents just published in that accurate and trustworthy journal, the *Railroad Gazette.* This summary shows that the number of butting collisions on the open road, directly caused by mistakes in and concerning telegraphic train orders, have increased in 1887, no less than *fifty per cent.* over the returns of the two preceding years. We give the precise figures from the *Gazette's* table.

Number of collisions in 1885	120
" " " 1886	127
" " " 1887	309

It appears upon investigation, that the greater part of these disastrous blunders are made at headquarters, that is to say, in the train despatcher's office, a point at which there can be no excuse whatever for inefficient service except that of false economy. It is nothing less than criminal folly to place even the temporary responsibility of controlling the movements of trains on an important railway, or in fact on any railway whatsoever, in the hands of a half-grown boy, but it is nevertheless sometimes done, and the results are occasionally such as might have been anticipated. We endorse to the full, the opinion of our contemporary, that a road which cannot afford first-class talent in the despatcher's office has no right to run trains.

The destruction of life and property caused by 309 butting collisions in one year would go a long way towards paying for the necessary "talent" on the roads on which they occurred.

The *Gazette's* remarks on the same subject are very much to the point, and will bear quoting. The editor says :—

> There can be little doubt that many operators are too young and that some are too old, and that a little inspection would disclose numbers of them whose habits of mind and sense of responsibility are loose and unsystematic. These at least will bear looking after; and where the rule requiring the consent of the ruling train to be always first obtained, is laid aside or suspended simply from lack of offices, operators or despatchers, it will be well to consider whether the lives of passengers and trainmen and the reputation of the road do not demand an increase of facilities in this direction. Whatever be the system in use it cannot be too strongly insisted that those engaged in the issue and delivery of train orders should be under constant and careful supervision. This is unfortunately too often neglected, with resulting carelessness on the part of operators and trainmen in this important branch, until attention is called to the deficiency in management by some serious calamity.

We do not know whether this subject is one which properly falls within the jurisdiction of the inter-state commerce commissioners, but it is very certain that a searching investigation by some competent authority is very much needed. The figures proclaim this so loudly that it hardly seems necessary for us to enlarge upon it.

Under the title, A Warning from the Edison Electric Light Co., appears a well written and well printed pamphlet of 84 pages, put up, not inappropriately, in covers resembling in color a Chinese fire-cracker. In this publication particular attention is paid to the case of the Consolidated Electric Light Company and "its new partners, Mr. George Westinghouse, Jr., and the Thomson-Houston Electric Company." The validity of the Edison lamp patents is affirmed over the signatures of William M. Evarts, Clarence Seward and John C. Tomlinson; the futility of all guarantees in behalf of any other electric system than that of Edison is pointed

out; the utter and absolute inutility of the alternate inductive system of electric distribution, is fully established so far as language is competent to effect that end, and the public is solemnly warned against the disastrous results, physical and pecuniary, which will be entailed by its use.

In the appendices, it is satisfactorily established that the first cost as well as the working expenses of the alternate system are much greater than that of the direct system of distribution, and in connection with this subject the following conundrum is propounded :—" It will be interesting for the Westinghouse enthusiast to glance at patent No. 278,418, allowed to Mr. Edison, May 29th 1883, for translating electric current from high to low tensions, and to speculate as to whether, if there were any financial value to the Westinghouse claims, the Edison company would allow a competitor to revel in undisturbed enjoyment of it."

We have speculated "as to whether" and frankly say that we give it up. But it is still more difficult for us to understand why it should be deemed necessary for the president of the Edison Company to issue such a grave proclamation against a competitor which offers a system not merely worthless and dangerous, but one which is sold at a higher price and costs more to operate, while at the same time it creates exasperation—not unmixed with terror— among its consumers, wherever it is in use.

The usual list of 345 Edison patents concludes the *brochure*, and will be found valuable for reference. We presume Mr. E. H. Johnson, president of the Edison Company, 16 Broad st. N. Y., will be pleased to furnish copies of the work to all seekers after the truth.

THE illustrated journals and magazines are paying considerable attention to electrical matters at the present time. In *Harper's Weekly* of February 25th, Mr. S. S. Wheeler has a very interesting article on Recent Developments of Electricity as an Industrial Art, in which the leading features in the modern developments of electrical science are sketched with a facile pen. The accompanying illustrations are numerous and excellent. Mr. F. L. Pope, writes of the Electric Motor and its Applications in the current number of *Scribner's Magazine*, giving a historical sketch of the evolution of the electric motor, and a succinct account of some of its already numberless modern applications. It is interesting to note that the true place of the electric motor, in the domain of mechanics, though early foretold by Professor Joseph Henry, has only been properly appreciated within the last fifteen years. This article is embellished with portraits of Ampère, Arago, Werner Siemens and Page, as well as with examples of stationary and railway motors. The same author will have an illustrated article in the April number of the *Century* magazine on the American Inventors of the Telegraph, in which special prominence will be given to the contributions thereto of Alfred Vail, which have never received the consideration which their importance deserves. Much unpublished material has been drawn upon, both for text and illustrations, and the paper will form an important contribution to the history of the electric telegraph in America. The illustrations will be abundant, and of the finest character. The publication of such papers as these will serve still further to stimulate the growing popular interest in electrical industries.

THE reception given by the Electric Club, at the formal opening of its house on the evening of January 31, was heartily enjoyed by a large company of members and invited guests. The ceremonies and festivities have been fully described in the daily and weekly press. We regret that we have not space to reprint the admirable address by Professor Rowland on "The Electrical and Magnetic Discoveries of Faraday," which constituted so prominent a feature of the evening. The club house has been decorated and furnished with much good taste, under the enthusiastic direction and supervision of Mr. H. C. Davis, the president. The conveniences and pleasures provided by the club, will doubtless be highly appreciated and largely availed of by members and friends.

IT is to be hoped that the distinction between legitimate journalistic enterprise and vociferous buncombe, seasoned with unwarrantable brag, which is so little observed by some leading daily newspapers, will not be obliterated in the management of any technical journal.

A circular recently issued by the publishers of an electrical periodical, which in many respects deserves and receives praise and support in electrical circles, savors too strongly, we regret to say, of disingenuous journalistic bluster. If reports are to be believed, the questionable circular led to an unseemly personal altercation at Pittsburgh, during the Electric Light Convention, between rival journalists. Why not leave the brag and bluster, brethren, to the quarreling dailies, and keep serenely in mind the constantly expanding field of electrical arts, in which there is likely to be room and verge enough for all to do good work and earn their money for some time to come.

IT is very painful to be constrained in the interest of justice, to publish information reflecting upon an American inventor; but disagreeable things have to be done sometimes. Our attention has been called to an article on the "Jack-knife" switch in the "Dictionaire Théorique et Pratique d'Électricité et de Magnétisme," now coming out in Paris, in which the following statement is made: "This name was given it because at the start the contact spring was arranged like a knife-blade, and because the invention was due to a French Canadian named Jack."

The "Jack-knife," now a curious relic of early telephone-exchanges in America, is still used by the French, who have doubtless carefully investigated its origin. Will not Mr. Scribner, who has hitherto been credited with the ingenious contrivance, now feel called upon to confess, and disclose the surname of the Canadian Jack, from whom he purloined the invention?

THE growth of the American Institute of Electrical Engineers keeps pace with the increasing spread of electrical work. The membership roll has more than doubled since the annual meeting ten months ago, and the rate of increase is steadily maintained from month to month.

Dr. Duncan's paper on Alternate Current Motors, read at the February meeting, and which we print in this issue, treated clearly and instructively a most timely topic. A very interesting feature of the discussion that followed, was Lieutenant Patten's design for a motor on the principle set forth by Professor Thomson at the Institute last May.

ARTICLES.

MR. R. EICKEMEYER'S DYNAMO.

In a notice of Mr. Stephen D. Field's motor experiments on the Thirty-fourth street branch of the elevated railroad, in the October number of the Electrical Engineer, it was mentioned that the current was furnished by a dynamo designed and constructed by Mr. R. Eickemeyer, of Yonkers, N. Y.

The illustrations in the present article show a machine of this type. It has been called an "iron-clad" dynamo, and an examination of the illustrations shows that it is in fact iron-clad throughout.

Figure 1 shows the machine complete, and figure 2 is a view of the same machine with one side of the iron covering removed.

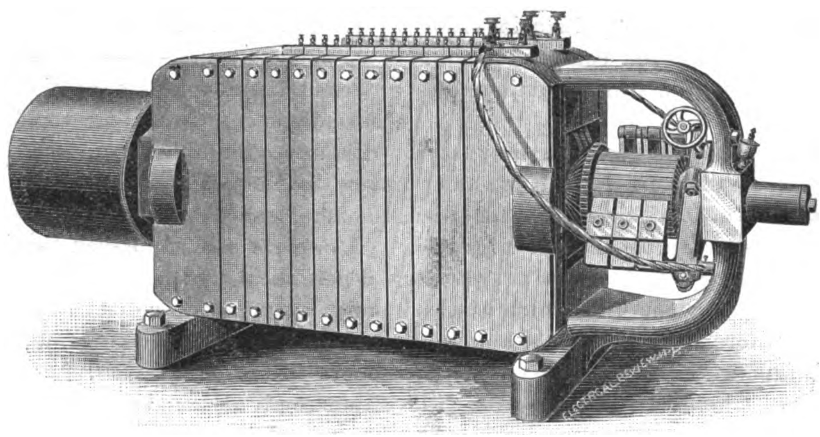

Fig. 1.

It will be seen that the armature is enclosed in the field coils, and that its core is in reality the electro-magnet, the iron covering forming, as it were, the yoke pieces, completing the magnetic circuit. The field coils thus enclose the armature and are in turn enclosed by a rectangular iron frame, forming part of the magnetic circuit, and constituting the backbone of the machine.

To furnish a proper support for the commutator end of the armature shaft the frame is extended beyond the field coils, and encloses the commutator and brushes.

The field winding is composed of a number of coils separated by spaces, to allow a free circulation of air; provision is also made to allow variations in the connections of the field coils for regulating purposes. A hand screw is provided by means of which the brushes, which are of the usual type, can be accurately adjusted.

Figures 3 and 4, which represent cross-sections of the machine, show in detail the relative position of the armature, field coils and the surrounding shell. This disposition of the field coils, causes all the lines of force produced by the current in the field coils, to pass through the armature core and to complete their circuit through the outer cast iron shell.

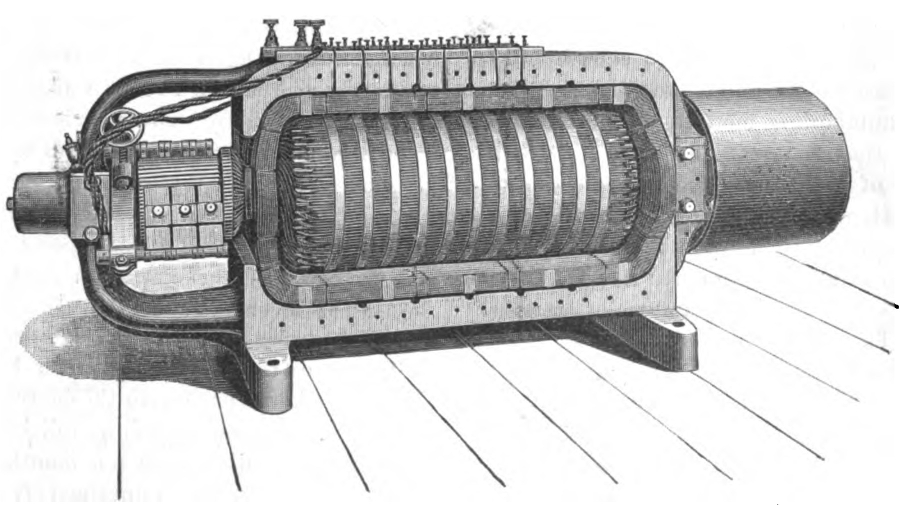

Fig. 2.

If this shell is of sufficient cross section no lines of force appear on the outside, and all loss by leakage is prevented, and as the whole frame serves as a carrier of lines of force all the cast iron in the machine serves a useful purpose, not only as a frame but also as a part of the magnetic circuit.

While the machine thus differs radically from dynamo machinesof the various types heretofore constructed in the disposition of the field wire, it also differs from them in the form and method of its armature winding.

The armature of the machine shown in figures 1 and 2, has 44 coils of four windings each. These coils are wound upon a shaping frame, and when finished and thoroughly saturated with insulating material, are placed upon the cylindrical core, secured by the pins at the ends and bound around the circumference in the usual manner.

To cover the drum or core after the coils are made, or to remove the coils again, is the work of but a few hours. To wind the coils on the shaping frame is a very simple operation, and can be performed by ordinary workmen very rapidly.

Figure 5 represents an armature covered with 44 coils of eight turns each, and figure 6 shows one of these coils.

The advantage of this armature winding, aside from the facility with which the coils can be made and put in position on the drum are:

All the coils of the armature and every turn of every coil are absolutely of the same length.

All the wires in each coil and all the coils on the armature are parallel to each other throughout their whole length.

The coils when wound are ready to be covered with insulating material, and can be tested thoroughly before they are put on the core. Should a defective coil be discovered after the armature has been completed, or should any coil become defective by accident, the coils can be readily taken off, the defective coil or coils replaced by perfect ones, and the whole put back on the armature again in less time than it would take to unwind an armature of the ordinary construction.

Another feature in favor of this mode of winding an armature is that the wires leading across the ends of the drum occupy less than half the space the same quantity of wire would occupy in the ordinary methods of winding armatures, and each coil lying parallel to the preceding one (throughout its length not a single wire crossing any other) the danger of burning out the armature is reduced to a minimum.

The above shown method of winding armature coils and inclosing the armature in the field coils, is also applicable to machines having four or more poles, and this furnishes a means to produce an armature absolutely balanced mechanically as well as electrically. The tests made on machines of this type, indicate that the quantity of material required to produce a given out-put is less than two-thirds of that necessary in a machine of the ordinary form.

The machines being perfectly balanced mechanically, magnetically and electrically, there is no sparking at the brushes, and a change in the adjustment of the brushes is only required with extreme variations of the current taken off, and is even then very slight. The efficiency is as high

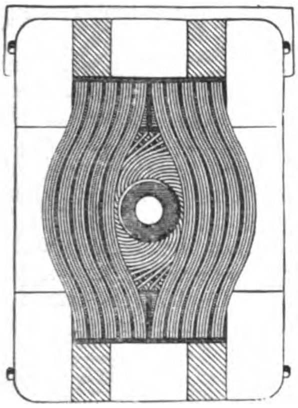

FIG. 3.

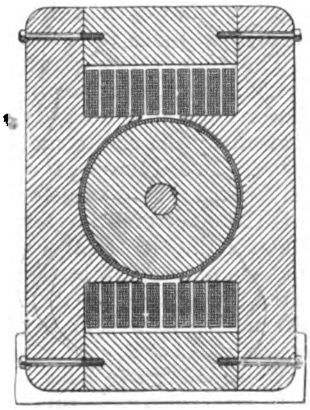

FIG. 4.

as in the best machines constructed. From a mechanical point of view, it appears that all the parts are securely protected, and yet are easily accessible. The machine as a whole, is compact and strong, and may be easily taken apart and remounted.

work, and I made many attempts to devise some method of simplifying the operation. Finally I perfected the winding as now made. The first large machine built was the one used to furnish the current for Mr. Stephen D. Field's motor, tried on the elevated railroad. Its performance far exceeded our expectations. The absence of sparking at the commutator showed that the machine was as well balanced electrically as could be desired, and, all in all, the machine seemed to be a step in the right direction.

"My electrical experiments covered the space of a good many years, for they were only carried on at odd times, when they did not interfere with our regular business—the manufacture of hat machinery."

ALTERNATING CURRENT ELECTRIC MOTORS.[1]

BY DR. LOUIS DUNCAN.

THE alternating system of electrical distribution, possessing as it does many advantages for distributing electrical energy over extended areas, possesses certain disadvantages, among others that of not, at present, allowing the use of electric motors for the distribution of power. Let us, before taking up the special subject for consideration to-night, briefly review the general subject of alternating current distribution.

In this system are employed currents of high and constant potential, varying from positive to negative many times a second. If we represent current and potential by curves whose heights above a horizontal line represent amperes or volts, the horizontal distance representing in-

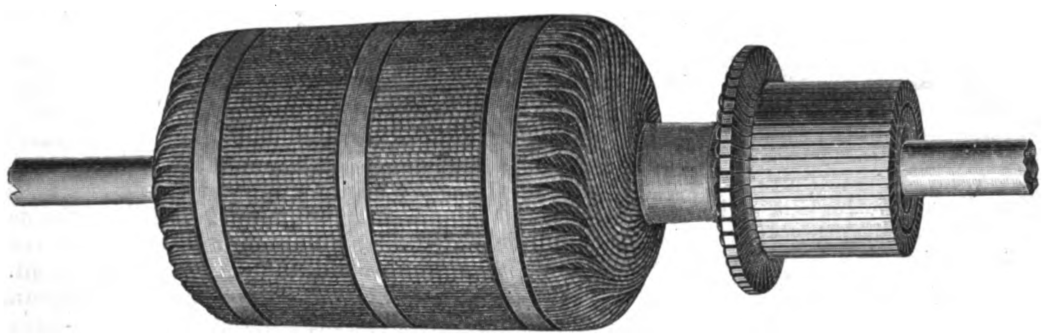

FIG. 5.

MR. EICKEMEYER, who has achieved a wide reputation as an inventor and manufacturer of machinery, for the manufacturing of hats, an industry which he may be said to have revolutionized, furnishes us the following note on the steps that led him to develop and perfect his dynamo.

"When Professor Bell astonished the world with his telephone I became very much interested in that new wonder and, like a good many others, I began to experiment.

"My experiments were on magneto-telephones, and the step

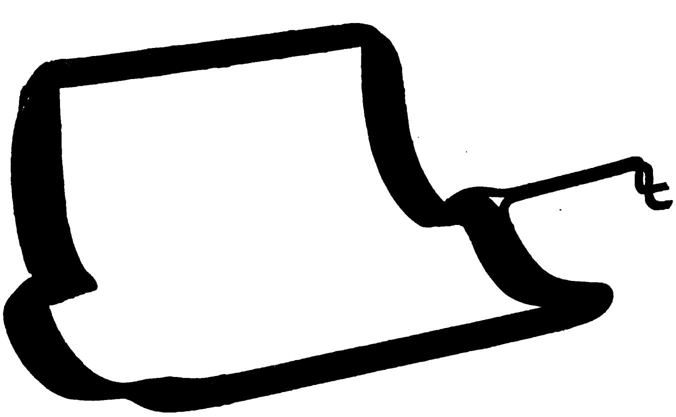

FIG. 6

to dynamo was a natural one. I made a great many dynamos of one type and another, steadily approaching the iron-clad form, and the machine as you know it is the result of experience gathered in their construction.

"The winding of the armature I found a troublesome piece of

tervals of time, we will have something like the following: Figure 1: II representing current, I representing electromotive force; the maximum value of the current lagging behind the maximum of E. M. F. in a way that you were shown recently by Mr. Stanley.

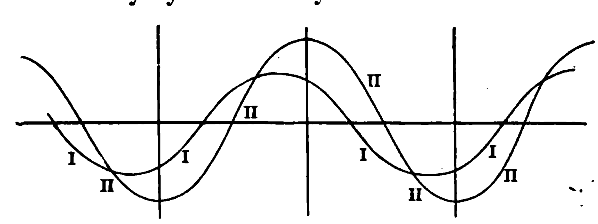

FIG. 1.

The high potential used in the dynamo or primary circuit would not be suitable for incandescent lighting and would be dangerous; it is, therefore, reduced to a low potential at points of consumption by "transformers;" that is, induction coils working backward. Now, the whole beauty of the system lies in this, that by using high potentials in the primary circuits we can transmit a great deal of energy with comparatively little current and, therefore, with little loss in the lines. This enables us to use small conductors and to avoid the large investment in copper necessary in distributing energy by the direct system.

In any central station supplying electric lights the full capacity of the plant is utilized but a short time during the day, and taking the whole 24 hours we will find that we

1. Read before the American Institute of Electrical Engineers, Feb. 14, 1888.

have sold an amount of energy equal to a half or a third—perhaps even less—of the amount we could supply supposing there was a demand for it all. Let us represent by a curve, figure 2, the amount of current used during the day in a constant potential system; the potential being constant, the energy will vary with the current, it being equal to E C.

The amount of energy we could have sold is represented by the total area A O X B; the amount we have sold is the area D E F G H I X O. If we had been able we would have three times the receipts, with expenses perhaps half again as much as in the first case.

A great problem before electricians is to fill the vacant spaces, A D E F G H A and H I B. There are two ways to partially accomplish this. Suppose, in the first place, we put electro-motors on the circuits and sell power during the day. What effect will that have on our diagram? If the motors are at work from 7 A. M. to 6 P. M. we can sell so much power as will at no time make the sum of the

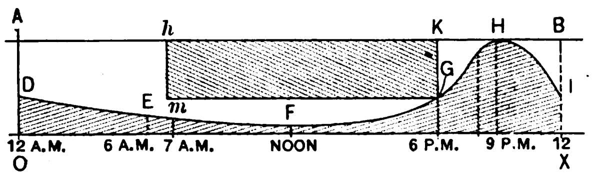

FIG. 2.

power and the energy used for lights greater than the maximum capacity of our station. The area representing the power we can thus sell is shown by G K L M on the diagram. The total solid part of the diagram is all that an alternating system can supply; the direct system could fill the entire area by using storage batteries.

Our knowledge on the subject of alternating currents is largely due to the work of M. Joubert and Dr. John Hopkinson. The latter showed first that alternating dynamos could be coupled in parallel, and afterwards that one dynamo could be used to drive another as a motor. He brought forward experiments tried by Professor Adams and himself, in which one dynamo had driven another, the latter doing mechanical work. Mr. Siemens at the same time, in 1885, described experiments where he had driven both alternating dynamos and ordinary series motors by alternating currents. Dr. Hopkinson's mathematical work assumes that the curve representing E. M. F. is a simple sine curve; that is, that $E = E_0 \text{ sine } 2 \pi \frac{t}{T}$; it is important to notice, however, that his principal conclusions do not depend upon this assumption, but would be true if the E. M. F. were any periodic curve. Since that time nothing of importance has appeared on the subject excepting two short papers, one by Mr. Kapp on "The Maximum Work Obtainable from a Given Source of E. M. F.;" the other by Mr. Blakesly on "Conditions of Maximum Efficiency in the Case of Transmission of Power by Alternating Electric Currents."

In all of the mathematical work done on this subject it has been assumed that the various E. M. F.'s may be represented by a sine curve, and that only simple electro-magnetic actions enter into the problem. I do not believe that these assumptions are true. Since Joubert's experiments, made in 1881, it has been known that the curve of E. M. F. of a Siemens alternating dynamo, where the external circuit had no statical capacity, was very nearly a sine curve. With some of the machines used to-day, and under the much more complicated conditions of distribution, this is probably not even approximately true. Neither is it true that the statical actions of the different forms of wire upon each other in the transformers can be neglected. Messrs. Hutchinson, Wilkes, and myself have lately experimented on this subject, and we have obtained the curves for the currents in the secondary and primary circuits under many conditions. These observed results do not agree with the results of calculation in the few cases that we have worked out. Until we have fully satisfied ourselves in this matter I will avoid any but the simplest mathematical work.

Alternating current motors are not in successful use; let us try to find out the difficulties they present and attempt to suggest plans for overcoming them.

The energy being transformed at any moment in any dynamo-electric apparatus—in which I include dynamos, motors, transformers, etc.—is equal to the product of the current by the electromotive force produced by the apparatus. In a dynamo, for example, the amount of mechanical energy being transformed into electrical is E C, where E is the electromotive force produced by the dynamo; in a motor the electrical work transformed into mechanical is e C, where e again is the E. M. F. produced by the apparatus, the counter E. M. F. of the motor. This is true for alternating as well as for direct current apparatus. Generally we have:

Work $= E\ C$. This is + for a dynamo — for a motor.

In alternating circuits E and C are constantly changing. If we represent them by curves, as before, we must multiply each value of C by the corresponding value of E, and if we add all these together from A to B, figure 3, we will have the work done by the current in one period. Now, if we consider values above the horizontal + and below it —, we have from e to d a + value of the product, from c to d a — value, from c to b a + value, from b to a —. The total work done then is $[e \text{ to } d] + [c \text{ to } b] - [d \text{ to } c] - [b \text{ to } a]$.

Now we see that if we shift II forward or pull I back, we have this work less even, though the curves themselves remain the same size. Now this is one of the exceptions I take to the alternating system. In a direct system as the work decreases the current decreases, and the heating of the mains becomes proportionally less, since it varies as C^2; for example, if the maximum loss in the mains of a direct current plant were 10 per cent. of the average, I imagine that the average loss is not over 3 per cent. In an alternating current plant, a decrease in the consumption of energy decreases the current very little; it simply shifts its position with respect to the E. M. F., and the heating, approximately equal to $\frac{C_0^2}{2} R$, remains nearly constant. A maximum loss of 2.5 per cent. would probably mean an average loss of at least 2 per cent. This same remark applies to

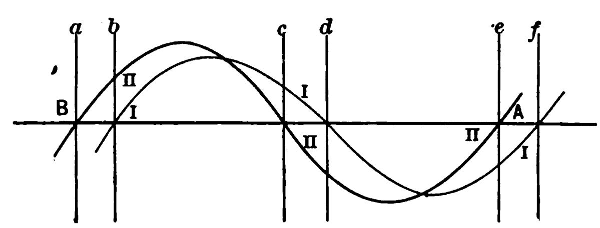

FIG. 3.

transformers and motors, and the average efficiency of the former will be considerably less than the maximum efficiency.

A distinction between continuous and alternating current apparatus is this: In continuous current dynamos and motors the cores making up the windings of the armatures make different angles with the lines of force in the field, and the result, when the armature rotates, is a constant E. M. F. fluctuating but little; in alternating dynamos and motors the alternate coils are symmetrical with respect to the alternate poles, the remaining coils being symmetrical with respect to similar poles of opposite signs. The result is a varying E. M. F., changing as has been shown. In dynamos the effect of this is that the power applied either varies from zero to a maximum each period, or the armature changes its speed at different points and oscillates with a period equal to that of the E. M. F.

Let us now consider what takes place in the case of two motors, one continuous, the other alternating, one between mains where a constant continuous E. M. F. is maintained, the other where there is a constant alternating E. M. F. In the first case representing current and E. M. F. by curves, we have been doing, we will have two straight lines, fig-

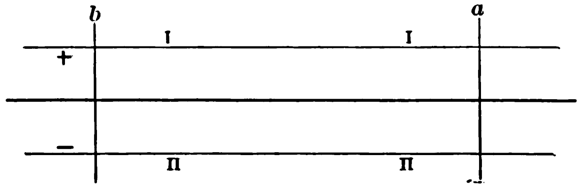

FIG. 4.

ure 4, one above, the other below our horizontal axis, the former representing current, the latter the counter E. M. F. of the motor. Reckoning time along the axis we have for the energy transformed in the interval from a to $b = -$ $C\,E$. As this is — it means that electrical is transformed into mechanical work.

Now, let us consider an alternating current motor built like an alternating dynamo, the field excited by a continuous current. If A B C, figure 5, are the poles of the field magnets, supposed to be excited by a continuous current, then the curve II will represent the counter or motor E. M. F. If our motor is running slowly there will be two or three reversals of current in the time it takes a coil to go from A to B (figure 6), and the product C E will be nearly

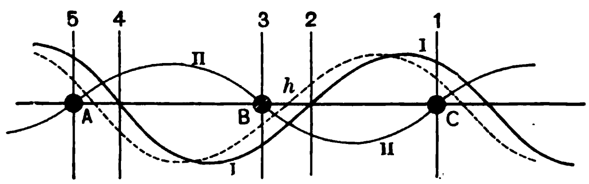

FIG. 5.

zero, the positive and negative parts being almost equal. Whether it is + or — is somewhat a matter of chance, and if it is — from A to B it will very likely be + from B to C. Thus the armature is pushed first in one direction then in the opposite, and there is no definite tendency for it to rotate as a motor. This brings us to our first difficulty, a simple alternating current motor will not start itself. Let us suppose, however, that it has been started by some means and has reached such a speed that in the time of a reversal a coil shall have moved over the distance between two similar poles. We will have the state of things in figure 5, and the armature will continue to rotate. Now the position of the curve II is fixed; we will consider the position of I as determined by the position of the armature coils when the current in them is zero; for instance, if the speed increases a little the curve will advance as shown by the dotted line. The total work transformed is the product of the two curves; from 1 to 2 it is —, from 2 to 3 it is +, from 3 to 4 —, from 4 to 5 +. The result is

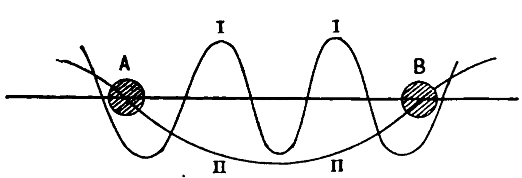

FIG. 6.

— [1 to 2 + 3 to 4] + [2 to 3 + 4 to 5]; part of the time then the machine is working as a dynamo, part of the time as a motor; the difference of the values represented by the brackets gives the mechanical work that is really available. Now while the available work is the difference of these areas, the difference becoming small as the load is decreased, the heating is the *sum* $C^2\,R$ for all the values of the current, and is independent of the position of its curve, as has been pointed out above.

Looking at the figure again we see that from 1 to 2 the armature is pushed forward by the current in the line; from 2 to 3 it is pulled back, since it is acting as a dynamo feeding into the line and can only get the energy to produce the current by decreasing its speed and drawing from its energy of motion. The armature oscillates then, and it is evident that the amount of its oscillation depends on the kind of work it is doing. If it is driving heavy wheels or machinery having considerable inertia it will only have to slow down slightly when it becomes a dynamo. If it is lifting weights the amount of oscillation will be considerable.

It is evident that there is a certain position of the curve I, that will make the available work a maximum. If the motor is doing all of its possible work the curve will take

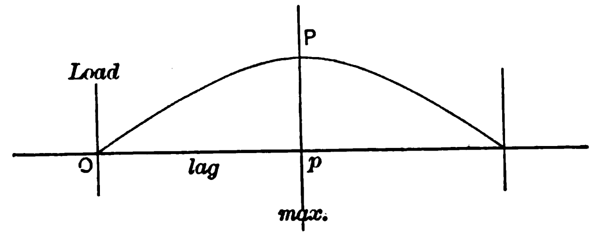

FIG. 7.

up this position; as the load is decreased the speed will increase for an instant until the curve has shifted forward into such a position that the sum of the products — $E\,C$ is equal to the work done. In fact, we can plot a curve representing values of the distance from the point the current curve crosses the axis to the same point when the work is zero corresponding to different loads.

Now the value of this lag, as we will call it, cannot be greater than O P, figure 7, for, although we might extend the curve on the other side, yet a slight increase in our load will cause the armature to fall back, decreasing the available work, and suddenly stop. It is, in fact, in unstable equilibrium.

Suppose we have found the value of the lag that will give us a maximum value of the work, and have calculated this value by the ordinary mathematical methods employed, the real work we can obtain is less than this, for

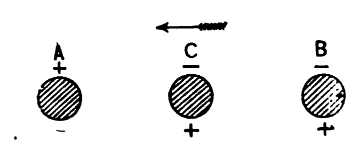

FIG. 8.

the current curve oscillates on both sides of the maximum, supposing we *could* work at the maximum; that is, it is only for a very short time in the best position; so that if we take the sum of the work for a period, it will be less than the calculated maximum. In reality we must work slightly in advance of the maximum, for if we were too near it the curve would fall behind P, and will then be in unstable equilibrium and stop. The practical maximum will then vary according to the amount of the oscillation; that is according to the nature of the work being done.

It seems to me that the possible forms of alternating motors are: (1) ordinary series motor; (2) an alternating dynamo reversed, the field being excited by a continuous current; (3) an alternating dynamo reversed, the field being excited by the alternating current first adjusted by a commutator on the shaft; (4) the arrangement suggested by Professor Thomson, which is described below.

In the first type—a series motor—there is no difficulty in starting; the motor will start of itself. There are these troubles, however: the armature and field must both be

thoroughly laminated to prevent eddy currents; the magnetism of such large masses of iron being rapidly reversed will cause losses unless both field and armature are far from saturation; that is, the mass must be great. Again, Mr. Kapp has shown that to obtain the maximum work we must have, approximately, the counter E. M. F. of the motor equal to the E. M. F. of self-induction—a condition almost impossible to realize in practice. The motor must be governed in some way, as it will not govern itself.

The alternating motor with a field fed from the alternating circuit, the current being commutated, will start itself. I do not know if this has been generally recognized. If, in figure 8, A and B are poles and C one of the armature coils, the effects of the currents will be as shown by the two sets of signs. The effect of either arrangement is to move the armature in the direction of the arrow. When C gets opposite A the commutator changes the relative directions of the currents in C and A, and C is repelled by A and the armature continues to rotate. The maximum work will, I think, be done when the speed is such that a reversal takes place in a distance A to B. The mathematical investigation is difficult, and until I am satisfied as to the assumptions usually made I will not attempt it. We have as an advantage of this type that it will start itself; a disadvantage is that the fields must be carefully laminated, there is loss in reversing them, and there will be for some speeds considerable sparking at the field commutator. I should not imagine, either, that the work obtainable from such a motor would be as great as if its field were fed by continuous currents.

The motor obtained by reversing an ordinary alternating dynamo has advantages and disadvantages. It perfectly regulates itself and the field magnets need not be laminated; that is, it can be made cheaply. It will give a greater output from a given source of current than corresponding machines of either of the types already discussed. Its disadvantages are, that it must be started independently. We must have a continuous current to excite the field, and if a load having any considerable inertia be suddenly applied the motor will stop. This last objection, by the way, will apply to the type of motor previously discussed, provided, as I have supposed, the maximum work is obtainable when the counter E. M. F. has the same period as the applied E. M. F.

Let us see what means we can employ to start the motor and excite the field. We could start by passing the commutated alternating current through the field as in the second type of motor discussed, changing our connections when the proper speed is attained, so that a continuous current from some external source passes through the field and the alternating current is shut off from it. Another way would be to have on the same shaft with our main motor a motor arrangement such as was described by Professor Elihu Thomson in his valuable paper on alternating current phenomena, read before the Institute. With this arrangement we can do more than start the motor. Professor Thomson pointed out that when this auxiliary motor reached a certain speed it would produce a continuous current in the external circuit of its armature. This current could be used to excite the field of the main motor. By properly proportioning the number of coils in the main and auxiliary motors, this continuous current would be produced just when the motor had arrived at its proper speed, and it is evident that we can make this current operate an automatic device to make the circuit of the main motor at this moment. I should imagine, however, that a motor made in this way would be expensive and not particularly efficient.

What seems to me the simplest, cheapest, and most efficient means of running alternating current motors is this: build the motor on the same general plan as the dynamo, with such modifications as the different conditions of working impose, and start it and excite the field magnets from a continuous current circuit, run with our alternating circuit, supplied with current by a dynamo at the central station. If we wish to distribute 500 h. p. our continuous circuit should have a maximum capacity of about 50 h. p. To start the motor we should have the following arrangement: there should be two breaks in our armature circuit, one between the regular brushes of the machine, the other at a commutator for the continuous current. At this second break the two ends of the circuit should be taken to alternate bars of the commutator, the number of bars being such that the direction of the current is reversed every time a coil passes a pole. The alternate bars are normally connected by a metal ring pressed against them by a spring; in this case we will have the normal circuit just as if there were no continuous current commutator. On the motor would be a switch-board that would accomplish the following things: If we wish to start we turn the handle of the switch to a certain position, this will short circuit our regular brushes and by the aid of a couple of levers will drop the continuous circuit brushes on the commutator, at the same time pulling away our metal ring. The motor will then start as a continuous current motor; when it has reached its proper number of revolutions or is above it, turn the handle a little further, the continuous current brushes will be raised, the metal ring will connect the commutator bars, and the alternating circuit will be made and the motor will continue to run and will do work.

Now, I consider that the advantages of this plan are these: It makes the motor simple and cheap to build; it will be more efficient and have a greater output than the other motors that have been discussed; the currents to excite the fields will have to be supplied anyhow, and they cannot be supplied more economically than from the central station; being simpler, there will be less liability of derangement.

The motor described by Professor Thomson, that I mentioned above, consists of field magnets through which the alternating current flows, with an armature not in any way connected with the external source of current, but which has currents induced in it just as if it were the secondary of a transformer. The circuits of all of the armature coils are open excepting one that is in such a position that the current induced in it will be repelled by the pole-pieces. In this form I do not think the motor will be particularly efficient or give any considerable output. It is possible that the principle may be further developed to give a considerable output, but I do not believe that any motor in which the field is fed by alternating currents can be cheaply made, although this is a matter of which I have no experience.

To prevent motors stopping when the load is thrown on it would only be necessary to drive the load from a friction pulley on the shaft of the motor. The pulley should be so adjusted that it will turn just before the motor falls behind the point of its maximum work.

It is possible that all of the plans I have suggested have been tried by the different inventors who are at work on this subject. If a motor of each type that I have mentioned were built and proper experiments were tried upon them, we would—provided we had the ability to interpret and apply our results—have the data necessary to design the best possible machine of each type, and if we build these it should settle the question as to which form will be the best. There is no necessity in building an indefinite number of motors to experiment with. It is too much the custom, if we wish to design a dynamo for instance, to build twenty different ones and see which is best. One machine, with proper experiments and deductions, should put us on the right track.

Dr. Holmes once said that when he had written anything that pleased him it immediately seemed very old indeed. I, with humility, feel much the same way, as if what I had said this evening is so apparent that every one must have known it. I can only hope that some of the suggestions I have made will help the development and final successful application of the alternating current motor.

ELECTRICAL KILLING

BY THOS. D. LOCKWOOD.

OUR friends of the Pulvermacher type, who "make, use, and vend" electric belts, and also the quasi-scientific gentlemen of whom Sir William Snow Harris used to say, with gentle mirth, that their knowledge of electricity was chiefly of the *negative* kind, continue, despite their little disagreements, to write informing us that "Electricity is Life"—this in large type.

What is to become of this beneficient theory in the event of the enactment of statutes in New York state, declaring that electricity is henceforth to be death, is as inscrutable as that other deep and dark mystery—the fate of a member of the British House of Commons after he is named by the Speaker. We learn from the daily and electrical press that the New York Legislature appointed a commission to consider the propriety and advisability of adopting some more humane method of inflicting capital punishment than hanging; and that the commission have recommended electricity as a substitute for the gallows.

This doubtless from the point of view of the commission, is reasonable and laudable. Their good intentions are not to be doubted. Being Americans, they read the newspapers and find out that escaping electricity occasionally kills somebody or something; and they doubtless share the general, but unverified assumption that death by electrical shock is painless.

The use of electricity is recommended by the commission as being more humane. We are left in doubt as to the recipient of the greater degree of humanity. Is it the sheriff, the spectators, or the convict himself? Probably the latter is intended to be the chief beneficiary of the improvement in humanity.

Modes of capital punishment differ widely with races and periods. In France the close shearing knife of Dr. Guillotin is still employed. Spain uses the axe and the garrote. The United States and Great Britain stick to hanging. The Romans had a wide choice of methods; while one very elegant mode utilized by the Greeks, was the method adopted in the case of Socrates—the cup of hemlock. The degree of humanity possessed by any of these modes is an unknown quantity; and there are not wanting scientists and others who maintain that hanging is, and must necessarily be an absolutely painless death. So far as can be ascertained, we have no data gleaned from personal experience which can positively assure us that a death accomplished by the swiftest and most intense application of electricity conceivable, would be altogether painless.

What is the object of the death penalty in the 19th century? Is it for punishment, or is it because it is considered that the only protection for society from further violence is to place the murderer where he cannot possibly commit other crimes? It would seem that both reasons share in the policy of retaining the death penalty for murder. If it were retained only for the safety of society, this could be achieved by a perpetual imprisonment with some statutory or constitutional bar against pardon. If, on the other hand, the idea of retribution be the controlling one, and if it be decided that the death penalty must be retained, must it not also be conceded that the terrors which are inseparable from it, do in effect keep the murder rate down, and deter many from committing murder, who would otherwise be perfectly willing to shed human blood on the slightest provocation? May we not also go a little further and say in view of the above, is it worth while to diminish these terrors by practically telling the murderer, that while we feel it our duty to put him out of the way, we will try to make the passage for him as easy as possible; in fact, absolutely without pain? Why so much solicitude in behalf of the convict?

If painlessness, or a more humane method be all that be desired, or if a superior degree of elegance be thought requisite (and it may be admitted that hanging cannot be regarded as elegant), why not go back to the Roman style of opening the veins of the criminal in a hot bath. Or suppose we adopt the Socratic plan and give our murderers the cup of hemlock? Or what reason can be given in favor of electricity, that does not apply with equal force to a death by the extreme application of chloroform, which would probably be about as humane as any plan can well be.

Electricity lights our streets and houses and propels our street cars; we can communicate both by signs and words through its far-reaching power; we can produce and reproduce forms and figures of marvelous beauty by its action on metals and their solutions; we have caused it to report fires, and to catch burglars; and if we may believe a story which I first read in 1856—and have continued to read at intervals ever since, we can cut down trees with it; but we have not yet pressed a key or a push-button for the deliberate purpose of killing anybody. The recommendation of the New York commission seems to be a cold blooded proposition for the degradation of a noble science; and moreover one which is entirely uncalled for.

Will the electrical engineers of the United States hail with joy this new proposition for the utilization of electricity? Will the *vril* of the Coming Race at last find its realization? Shall we indeed have a trade in execution supplies; and following the lead of the older crafts: "the United States Electrical Execution Association; the American Institute of Electrical Executioners; the Old-Timers Association of Electrical Capital Punishment?" Shall our electrical journals of which we are now so justly proud be obliged to record the invention of new and improved systems for scientific killing! and be filled with advertisements of "complete plants for electrical executions, including dynamo, wires with black insulation, adjustable easy chairs with terminals, commutators and condensers, together with double flexible cord, and all other apparatus required?" And which of us in our clubs and institutes will feel like shaking hands with the expert whose business it is to set up wires, arrange dynamos, fix a criminal properly in his seat, and send the final quietus through his nerves? I for one acknowledge that my flesh would creep at the idea of such a greeting. I hope that the recommendation of the New York state commission will not be adopted.

After carefully considering the subject, it certainly seems to me that electricity is too noble a science to be thus lowered to the most ignoble of uses, and that its votaries can not, should not, and will not endorse the experimental desires of the Albany commission, composed though it be of such distinguished gentlemen as Messrs. Gerry, Hall and Southwick.

The commission in its report, tells us that Dr. Fell, and others, have made certain observations from which they make practical deductions which have aided them in reporting as they have done. Somebody once said "I do not love thee, Dr. Fell," and then professed ignorance as to the reason for his lack of affection. The clue appears now perhaps to be within our grasp.

Let us keep electricity as clean as we can. It is bad enough to have it kill a man once in a while unintentionally as it were; but to cause it to become the instrument of deliberate homicide, even though the killing be legalized, is to my mind an intolerable suggestion.

Illuminating gas is a bad smelling compound, and has a reputation not of the cleanest, but nobody has yet seriously proposed to make it an instrument of capital punishment.

The subject has been handled by Mr. W. D. Howells, in *Harper's Weekly*, and so far as I can make out from his language, he favors the use of electricity. Perhaps this is because he himself is not an electrician, but this does not affect my abhorence of the idea. I can tolerate the idea of having telegraph messages sent to me while I

am traveling on a train, although I don't hanker after that degree of civilization. I am willing to pardon the idiosyncracies of a night telephone operator who calls me up at two in the morning to tell me that it is thirteen below zero; or to give me the inspiring intelligence that "Nicodemus Brown wants his horse," apparently under the impression that I am running a livery stable.

I can condone the horrible howl or the intensified screech of the electric light or power-circuit produced inductively on my telephone line when on a question of life and death I wish to use my telephone; I can even figuratively heap coals of fire on the head of an automatic fire alarm company, which though its thermostats are set at 150, persists in summoning the fire department every time that my cook fries doughnuts; and I can, moreover, by a stern effort of self repression overlook once more the imbecile and Sisiphian electrical yarn about the conduction of electricity from electric light wires down the stream of water proceeding from the nozzle of a fire engine hose, when the said stream impinges upon the said wires, and about the extreme danger of the fireman in consequence thereof. But I do not think I could forgive myself were I to engage in the business of killing by electricity. We must draw the line somewhere, and in the name of electricity in the service of man, let us draw it at capital punishment.

Papers Read Before the National Electric Light Association, Pittsburgh, Feb. 21-23, 1888.

INSULATION AND INSTALLATION OF WIRES AND CONSTRUCTION OF PLANT.

BY PROFESSOR ELIHU THOMSON.

I HAVE been requested to present my views on the above subject, and having recklessly allowed myself in spite of the many other demands upon my time to accept the chairmanship of your committee on the same subject, I have felt it my duty to at least, say enough to provoke a general discussion and interchange of views between others who may have given more special study to the matters in hand. My endeavor, therefore, will not be to arbitrarily lay down any rules but rather to point out directions in which information may be gained and improvements made.

The subject is very extensive in its scope and could not be dealt with except in a very superficial way in the time at our command, and, meanwhile, I feel constrained to state that I make no claim to the possession of any of the qualifications which would be requisite for thorough work on the subject.

In the installation of the electric light or power plant, we first of all find that the conditions vary very widely. Its size, location, the distance covered, or length of circuits, and the climatic effects met with, need to be considered.

Then again the nature of the plant itself, whether arc light, direct incandescent, alternating system with transformers or converters, governs to a large extent the conditions of the installation of the wires and of the plant itself. We may, of course, find in a single station or installation representations of these and other characters of plants, such as medium potential circuits for power transmission alone.

Three or four years ago we should have been required only to take into account simple cases of high potential for arc circuits, and low potential direct currents for incandescent multiple arc circuits, but the range now covered may be considered to be from any potential above 50 volts up to several thousands, and any current strength from about one ampere up to several thousand amperes.

In considering the proper insulation and installing of wires for conveying these potentials and currents we are required to still further extend our field of view, and divide them into aerial, or overhead wires or conductors, and underground systems, and each of these taken in connection with the conductors for indoor distribution to the lamps, motors or other energy uses. We have thus outlined the field which should be covered in dealing with a subject such as we have before us—Insulation and Installation of Wires and Construction of Plant would furnish as a subject material to fill a many paged volume and not by any means exhaust it. May such a work soon be forthcoming.

Concerning the relative merits of overhead conductors and underground conductors, it is pretty generally agreed that except for expense and the difficulties of insulation, and connections from the mains, the underground system would be preferable as avoiding unsightliness, and liability of interference either by leakage, induction, or contacts with the overhead wires. Now to preserve insulation of the lines conveying high potentials, which potentials cannot be avoided if distance is to be covered without conductors of such size as to have a prohibitive cost, is a vital question. It may well be conceded that when the potentials are very low, say 100 to 200 volts, the difficulties of insulation are very slight as compared with those of the use of two or three thousand volts.

It is a notable fact that so far as concerns the placing of overhead wires, particularly the wires of telephone, telegraph, and other such systems and in cases of electric light wires, extreme disregard of systems or orderly direction for such wires is the cause of much of the unsightly appearance presented by them and much of the liability to get out of order. The tendency is also to use very light and easily broken wires for telephonic work, such as may at any time come down upon the necessarily stronger electric light wires, strength being synonymous with efficiency in these latter.

It is thought that there is need of some rules, or enactments to render impossible the mazes of telegraph, telephone, private wires, fire alarms, live wires, dead wires, and electric light wires (which for our purposes may be considered very live wires), such as may be seen in many of our large cities.

Should the wires of all kinds be laid or hung in orderly bundles having a definite direction and only changing that direction by definite angles, such as right angles, in accordance with a prearranged system, I think that much of the objection now existing to the placing of overhead conductors could be eliminated. Add to this a requirement increasing the durability and tenacity demanded for telephone and telegraph wires and their supports, and the damages of leaks and grounds would in a large measure be removed.

Many trials have been made, and considerable progress has resulted therefrom, in the direction of securing an insulating covering for electric wires as may adapt them to the use of high potentials without leakage, and prevent contacts formed by abrasion with other wires. This appears to be one of the most difficult problems in electric engineering. The problem is not so much to find a first-class insulating substance for wire covering, but to find combined therewith, or to combine therewith the qualities of indefinite durability where exposed to the weather, and great toughness and power of resisting cutting or abrasion. For overhead work not only is an excellent insulator capable of withstanding very high potentials without leakage or rupture required, but such property must be retained along with the mechanical properties of hardness and toughness for indefinite periods. Besides the cost must not be too great.

To what extent any quality of insulating wire, or insulating material for out-door use, fulfills this requirement is a matter which it is difficult indeed to determine fully, particularly as a test for durability must necessarily require a long time to complete. Indeed, it would seem that our best guide must be the experience gained in the use of different wires on a large scale under different climate conditions and without extremes of heat and cold more or less great.

Aside from the insulation given to the wire by its covering, considered purely as an insulator, most stress must be laid upon the requirement of resistance to mechanical friction or abrasion, as tending to give immunity from grounds by contact with other wires or with tree branches, roofs, cornices, etc.

Toughness and elasticity of insulation are hence seen to be qualities of high importance.

Whether such mechanical tests as will represent the conditions of actual practice in the use of the wire in relation to abrasion and percussion, bending, etc., which may break through the coating of insulation, can be devised and applied to test wires is somewhat doubtful, though, without doubt, much information may be obtained in the pursuance of such an object.

The retention of the toughness and elasticity for a reasonable period, is, of course, demanded, and it is this retention which in otherwise excellent coverings is often found absent, the effect of exposure being to render the materials brittle and porous.

It has often been proposed to make tests for the insulation resistance of the coverings of certain lengths of any wire, taken as examples representing an average for such wires, under potentials somewhat exceeding that existing under actual use or practice and so to determine the insulating capabilities of different coverings, but it is my opinion that such tests are certainly useful and important, and, in the case of underground wires and cables, indispensable; yet, for overhead work, since most of the length of the wire is exposed to air only, which is a practically perfect insulator, and since the chances of leakage from the lines, arises most from imperfect insulating supports and from accidental contacts with other wires or surfaces, additional tests would in any case, be required to determine the suitability of an insulator for overhead lines. In this connection it may be stated that during thunder storms, overhead wires are subject to violent inductional effects giving rise oftentimes, to the momentary charging of the lines with potentials very far in excess of the potentials of any demands, and capable of breaking through the wire cover-

ing where it may be near, or touch a metal object or wet surface. This breaking through may give rise to a weak spot which will be followed by the dynamo's current itself, if of high potential, and if at the same time other conditions be favorable to a diversion of current.

When overhead wires or pole lines are required to pass through and between branches of trees, a condition not infrequent in many of our towns and cities, considerable difficulty may be found in preserving the insulator of the line, the covering of which is apt to be rubbed off by the tree branches swaying in the wind. Fastening insulators to the branches for support and attachment of the wires is an uncertain remedy, on account of the swaying of the tree taking place in different directions not transverse to the line of wire, so that the wire is strained or detached from its support along with the insulator by the violence of the actions. Many and ingenious are the devices which the over-zealous lineman makes use of to suddenly or gradually and mysteriously lop off the offending limb, when the case is exceptionally critical and permission for the amputation of the offending member cannot be obtained from the conservative citizen whose sidewalk supports the obstacle to the lineman's ambitions.

It is customary to thicken the insulation of the wire at such places as are threatened by abrasion by winding on it a wide band of tough and adhesive tape such as can now be found in the market. If neatly and thoroughly done the insulation of the wire may thus often be preserved under decidedly adverse conditions.

It must be admitted that the insulation of a high potential circuit can never be too good and that, therefore, any measure which may tend to its improvement and preservation is a double advantage, for not only are the dangers of grounds and leaks lessened but the power of the current to do useful work is assisted. A considerable leakage from a high potential circuit means indeed a loss of power or efficiency of the system. For instance, the loss of one-half an ampere of current at a potential of 1,500 volts would represent about one horse-power of current energy lost, costing more than a horse-power at the dynamo pulley to supply such a leak.

This latter consideration is of especial importance in dealing with the lines feeding transformers with alternating currents at high potentials.

With 1,000 volts in the primary circuit it is readily seen that a badly constructed or leakage line might easily cause the loss of a considerable percentage of current, such as would reduce the economy of the system more particularly when running under light loads, at which time it is desirable to secure and to keep up the best possible efficiency.

When wires or cables are to be laid underground their resistance to abrasion is of importance only when they require to be drawn into conduits or sections of conduits, but, when once placed intact, they are not necessarily further subject to mechanical inquiry, as they are generally surrounded by protective casings or tubes.

The total exclusion of moisture and the possession by the wire coverings of a high insulation resistance are requisites of great importance in such work. The difficulties are with low potentials comparatively easy to provide against, but in the case of wires at high electric potentials or pressures, such as arc light or alternating current primary lines, such difficulties are much exaggerated. The least access of moisture, such as may occur by flaws in the insulation, may result in the production of a bad ground; or a slight leak due to some original defect, may so improve itself by the passage of current as to become a bad fault, or a complete connection to earth. It would seem best, in all cases, not to place reliance upon the integrity and perfection of but a single insulating coating or covering for the wire, but to give it say three coatings successively applied, and which are in a measure independent coverings, all of them impervious to moisture and good insulators.

If composed of different materials, the peculiar liabilities to defect of one such coating may possibly be compensated by other qualities in another coating, so that there may be small chance of superposed defects in all coatings alike.

Let but the insulating capacity of each layer or coating be amply good to withstand the potential used, and it is difficult to conceive how trouble could arise from leaks due to defective portions of the covering. First cost is, however, a barrier to the perfection of underground systems, to save which cost, less effective and cheaper structures are often given the place which should be occupied by the more perfect and the more costly.

It is important that in cases in which overhead wires or wires above ground are connected with underground lines, efficient means for carrying inductive discharges to earth be provided, such as is secured by the use of proper lightning arresters; for faults may otherwise be produced in the best underground system of conductors, due to static inductivial discharges existing during thunder storms, at the moments of lightning discharge. These discharges are in overhead lines oft-times quite vigorous, and capable of puncturing moderate thicknesses of insulation. They are not to be confounded with actual passage of lightning strokes to the lines, which of course have an infinitely greater capacity for mischief.

The preservation of the insulation of *inside wiring* is not difficult where the potentials used are low nor is it difficult with the exercise of care and skill in the running of the wires and the selection of suitable courses for them to take, to install simple series lines, such as those for arc lights, which shall be practically exempt from leakage, unless abraded and brought into contact with conducting objects or moist surfaces involving leak to earth.

Unfortunately, owing to lack of skill and judgment and haste in installing, much of the wiring done is not as well done as it should be for the best results.

Distribution of current to groups of incandescent lights upon arc light or other high potential lines should always be undertaken with great care, and it is thought that such work should only be undertaken when exceptionally favorable conditions for avoiding accidental leakage exists; especially should the potential of the line at the dynamo exceed 1,500 volts, or an amount which would sustain 30 arc lamps in series. One of the important elements of safety in such installation is simplicity and ease of inspection of the wiring, and no concealed wires should be used in them.

Concerning the wires which are suitable for indoor work and particularly for high potentials, the endeavor has been to combine moisture proof and fire resisting, or rather incombustible materials in the covering. The difficulty has been to find moisture resisting substances which would not carry fire, and fire resisting or incombustible material which would not carry or absorb moisture. The two properties seem in most cases incompatible. The tendency now is to surround the wire with a first covering of moisture proof material of the nature of rubber, bitumen, resins, etc., and outside of this to place a second layer which will not carry fire.

For house to house and general incandescent lighting where the distance from the station is not too great, the direct low potential system possesses most of the advantages, the difficulties of leakage from the defective insulation being, of course, at a minimum; but where the distances are so great as to make the required outlay for copper in the conductors practically prohibit the extension of the system, a transformer or converter system, if of good design and economy, may be made to yield excellent results. In such cases the high potential primary wires need not enter the building, or when they do may be suitably protected, the house or inside lines being of such low potentials as to be run with ordinary precautions as to leakage. However, the integrity of the system would be changed should a connection or leak form between the primary and secondary wires of the transformer, thus connecting the local or house line with the high potential outside mains. Such a connection might easily exist unsuspected, and would be a constant source of menace or possible danger, not discoverable by the mere tests for grounds as applied to the primary line at the station.

The expedient of securely grounding the secondary or local lines was devised by me to overcome this difficulty. It insures immunity from the risks arising out of possible leak from the primary lines to the house lines, because such leaks are at once detected by the ordinary tests for grounds.

The consideration of the subject of what appliances are the best for the detection and location of leaks or faults in the insulation of conductors when they exist, and whether the ordinary crude methods are adapted to all cases by such detection, would prolong the present paper much beyond its intended limits, and it will have secured its object if it open up an opportunity or give occasion for a free consideration in the interchange of experience and ideas upon the general subject forming its title.

THE UNDERGROUNDING OF ELECTRIC ARC LIGHT WIRES.

BY WELLS W. LEGGETT.

(President of the Brush Electric Light Co., of Detroit, Michigan.)

THIS topic is one of absorbing interest at the present time. Municipal and legislative authority seeks to compel the burying of all the wires without discrimination, and to cast upon the parties interested the burden of finding a practical means to accomplish the end.

The progress of invention in science and art records, infallibly, the contemporaneous public demand. This demand discloses a necessity, and inventive ingenuity suggests the remedy.

Starting from this standpoint we find public wiring began with the telegraph.

In 1753, Marshall, of Paisley, evolved an electric telegraph wherein insulated wires were to be trained on poles, and so Lomond in 1787; Betencourt in the same year; Riezen in 1794; Cavallo in 1795; Salva in 1796; Sommering in 1809; Coxe in 1810, and Sharp in 1813, all had telegraphs, employing from one to twenty-six wires, trained on poles.

At this stage, however, the interesting experiment to which the world lent a helping hand, developed signs of commercial utility, and value. Man's cupidity and selfishness at once antagonizes what he cannot share, and we find the public arrayed in opposition to the use of the highways. Inventive ingenuity

came to the rescue, and in 1816 Ronalds erected and used a telegraph in which some of his wires were placed on poles and *some were buried in the ground.* Tribavillet followed in 1828 with a system employing underground wires, and when Professor Morse, in 1832, brought out his system, he proposed connecting Washington with Baltimore, a distance of 44 miles. To his mind the wire should be insulated and laid in a lead tube in the ground. He constructed his line with great care and at large expense; but only a few miles had been laid when the gradual escape from his line proved his scheme impracticable. He was about to abandon the undertaking when one of his coadjutors, Dr. Page, of the Patent Office, or Professor Henry, of the Smithsonian Institute, said to him: "Take your wire from the ground and train it on poles." The advice was followed and success achieved.

Here then in the incipiency of public wiring is the first recorded failure coupled with its remedy: "Take the wires from the ground and put them on poles."

With underground telegraph and telephone wires the electrical difficulties to overcome are much the same. Moisture must be excluded from the wires. Insulation must be good and induction be reduced to the minimum, especially between adjacent lines. In both, however, leakage from the lines due to imperfect insulation may be compensated within limits by additional battery force. The battery acts like a pump sending water through a leaky pipe, the water may all escape before reaching the discharge end—but with a more powerful pump, while increase of pressure will cause greater escape through leakage, one may succeed in discharging a limited quantity through the end of the pipe and so accomplish the purpose sought.

For this reason underground telegraph and telephone wires may be operated with a measure of success.

In most of our cities all telegraph wires might be led to a certain point from which the wires of all systems could by one underground conduit be led to a central station or stations, and thence back through the same conduit; and where the wires are numerous might warrant the expense.

With telephone companies whose subscribers are in all parts of the city, the requirements that each wire should be conveyed underground would involve an outlay for conduits wholly prohibitive.

For direct service incandescent lighting the required conductors are so large that to train them upon poles or to train an equivalent capacity—in smaller wires on poles—would involve outlay and annoyance exceeding that required to underground the conductors.

So again the resistance of the conductors to the flow of the current is exceedingly slight; it might be compared to the pouring of water from a pitcher through a six inch pipe—its course of least resistance lies right forward through the pipe, and there is little tendency for it to seek an exit through any other restricted channel.

In comparison with it the arc light current might be likened to a large hose with a small nozzle, through which water is being forced with a powerful pump—the tension is very great, and if so much as a pin-hole exists in the hose, water will squirt therefrom, and quickly enlarge the orifice to a fatal rent.

From the fact, therefore, that telegraph and telephone, and incandescent electric light wires may be trained underground with success, by no means does it follow that the same is true of arc light wires.

It is an undoubted fact that to successfully underground electric arc light wires involves simply and solely a question of expense. But expense may be of the very essence of the inquiry, for if the expense is out of proportion to the revenue that can be derived from the service, expense alone prohibits the outlay and determines it to be impracticable. Expenditure of money is alone required to tunnel the Dover Straits, and yet French and English capitalists have pronounced it wholly impracticable, as the returns could not warrant the investment. So it is with electric arc light wires; an efficient system, so far as inventive ingenuity has yet presented any plan, involves an expenditure wholly prohibitive, and for that reason alone is impracticable.

Electric arc lights may be employed successfully, trained in the air on poles, and an underground system is practicable which can reproduce the same conditions. Let us examine these conditions. All substances are conductors, as copper, iron, lead, rubber, glass, dry air. Some substances are such poor conductors that, in comparison with those that are better, we call them non-conductors, and the greatest available non-conductor is dry air. We use these poor or non-conductors, such as rubber, glass, paraffine, wood and dry air as insulators, and we find dry air to be our most perfect insulator. Dry air is a better insulator than rubber: if, therefore, in dry air two rubber covered wires cross in close proximity to each other, the induction is greater between them than would be the case if both wires were bare. But air is usually laden with moisture, and water, charged as it is with the mineral salts and acids of the atmosphere, is a good conductor. We therefore coat our line wires with an insulating material, to shield them from direct contact with moist surfaces or other good conductors, and so reduce in amount the current which is always escaping by connection to the ground, and which varies in direct proportion to the conducting property of the intermediate medium.

Where our insulated wires are trained on poles, we have at the rate of thirty poles to the mile, thirty points at which a small amount of current may and always does seep off to the ground.

Now let us put an insulated cable in a conduit in the ground. The conditions are all changed in the most aggravating manner. Instead of comparatively dry air, the air is clammy and heavily laden with moisture, instead of a mass of surrounding air as on the poles, the envelop of air is, at best, but an inch more or less in thickness. Instead of resting at thirty points in a mile on glass supports, connected to dry non-conducting wooden poles to make the passage to the ground as much obstructed as possible, the line touches the conduit at say two or three points in the space of every foot or at say ten thousand points in a mile, and the conduit itself, a much better conductor than glass or dry wood, is all that separates it from the moist earth.

The bearings at which the current may seep away have been multiplied from thirty contacts to ten thousand contacts per mile, while the conductivity of the medium at each point has been greatly enhanced. A regulating arched subway has been suggested, and approaches most nearly to a successful plan, but only a state or city could stand the necessary outlay. A subway of this character, four feet wide and eight feet high for Chestnut street alone, in Philadelphia, was estimated would cost the city $1,500,000. After completion such a subway would have to be supplied with forced ventilation to keep it dry. If then the insulated wires could be supported so as to touch at but thirty points to the mile, the conditions of exterior wire training on poles would be fairly approximated.

The question is frequently asked, if telephone and telegraph wires can be undergrounded, why cannot arc wires. The reason is plain, seepage or escape can be supplied in the former by additional battery power, but an arc light generator is a queer specimen of mechanics.

It starts a mild current, and this passing back around its field magnets, builds them up; the increased magnetism induces greater impulses in the bobbins of the armature; the current thus increased continues to pass through the line and back around the field magnets until the current has reached its maximum. It is, therefore, apparent that anything which seeps the current from the line, not only steals the quantity which has escaped, but prevents just so much current from passing back around the field magnets, and to that extent robs the machine of its capacity to generate a current. These machines are capable of taking care of the same amount of loss at the insulators in the pole and line system, but when this is multiplied many times as in an underground conduit, it is so robbed of its power to recuperate that the resulting lights are necessarily reduced in number and are weakly and sickly.

Operations looking to the undergrounding of arc light wires have been prosecuted on a large scale at New York, Brooklyn, Chicago, Philadelphia, and Washington.

Notwithstanding all reports to the contrary, I find that at New York, although the subway commission has expended vast sums of money and has succeeded in burying certain telephone and telegraph wires, no arc light line has up to this time been buried in New York city, and this is fully corroborated by the report of the board of electrical control of January 6th, 1888.

At Brooklyn, New York, the board of commissioners of electrical subways instituted thorough investigation of this subject in 1886, and in its report of December 30, 1886, says:

"With regard to electric light conductors this board has found no device which would, with certainty in its opinion, enable the wires carrying arc light currents to be safely and successfully operated in the same conduit with telephone and telegraph conductors without disturbance or injury to the latter.

"But the board desires to say, emphatically, that those fluent critics who talk of putting electric light conductors underground, making no distinctions between arc lights and incandescent lights or between the arc lights of different systems, are ignorant of the alphabet of the subject."

The president of the board visited all the principal cities in Great Britain and Europe; he found no arc light wires underground, and although a few years since such wires were trained in the Paris sewers, they have been removed and no arc light wires are now allowed therein.

The Brooklyn commission made another report, December 15, 1887, and on this topic say:

"As was fully explained in the last report, the subject of underground conduits for arc currents is the one which presents the most numerous and novel difficulties.

"Since it has been impossible for Brooklyn to take the lead in the experimental solution of these, the only remaining course was to watch carefully the progress of experiments in other cities. This has been done, both by correspondence and by personal visits of members of the board. The principal cities in which experiments of this kind have been in progress are New York, Chicago, Philadelphia, Baltimore and Washington. In one or another of these, several systems which were regarded with favor a year ago,

have since developed defects or even come to entire failure. It cannot be said that any system has yet been completely proven to be permanently satisfactory.

"There are one or two, however, which promise well, and this board awaits with attentive interest their further trial, regretting only its inability, through the cause already specified, to co-operate in the experimental investigation of the different and delicate questions involved."

There are no arc light wires underground up to this time in Brooklyn.

At Washington, in 1884, cables were laid in F street, from 9th to 15th. In a few months, it was necessary to dig up a few of the same. Later, there was much more trouble, and it was all taken up and relaid. About one year after the first laying, it was wholly abandoned, because they could not make it work.

In 1885, they laid cables on Pennsylvania avenue, from Ninth to First streets, and imported an expert from Antwerp to lay them.

Twelve cables were laid in solid cement, and no expense spared to insure success. They proved an utter failure. The avenue was dug up many times. The wires were in September, 1887, mostly out of service, and the remainder were in such bad shape that they would require constant repairing or have to be abandoned.

An officer of the Washington company, writes me under date of September 12th, 1887: "We have many committees coming here to see what we have accomplished, as they have heard that we have met with great success, and so forth. We will say to you, that our experience, after the outlay of many thousand dollars, is this: have nothing to do with underground cables for arc lighting if you can possibly avoid it. Many will tell you that it is perfectly practicable; look out for such parties: they are probably interested directly or indirectly in cables. There is a big lobby in that branch of business. There is no city or town in the world where a cable has been made to work two years that has been subjected to 2,000 volts of pressure.

This Washington company is using lead covered cables with success, for incandescent work; but as to the undergrounding of arc light wires, confirmed as late as February 7th, 1888, they report that out of 14 miles of arc light cable, in fourteen different circuits, all have proved total failures, and have been abandoned except a very small amount.

At Philadelphia, elaborate experiments have been prosecuted. All kinds of cables have been employed, and a great variety of conduits; great trouble has been experienced. The systems largely employed were such having ducts through which the cables were drawn—in most cases the insulating compound rapidly deteriorated and became useless—in others it would be rotted and become water soaked. Where lead covered cables were used in conduits where creosote was employed, the effect was to rapidly oxidize the lead covering and disintegrate the same. It was found that gas could not be kept from the ducts although apparently gas tight—many explosions followed. Recourse was then had to ventilation by lamp posts, but the trouble was not corrected. After several explosions in one system, in which persons and property were injured, a power fan was adjusted to force air through the conduit, deeming it better to do so than to draw the air through, which might simultaneously draw in gas. When shortly afterwards the lighting company was congratulating itself that it had overcome the difficulty, a tremendous explosion ensued, extending for a long distance, ripped up the street, and broke a large plate glass window. That entire system of lights had to be abandoned. It was some six months ago determined by the manager that as a result of experience, no conduit would suffice for arc light wires in which there were open ducts, and that success lay in the employment of lead covered cables buried solid. This plan, suggested by the city electricians, was tried and success seemed assured, but they now report the experiment unsuccessful. The section buried is not great, but three bad grounds have recently developed. Two were repaired, but the third necessitated the temporary cutting out of a part of the line and the training of wires on poles until the earth may thaw and enable access to be had to the wires.

The various companies of Philadelphia are at a loss what to try next. At this point, I would note that these demands for a system for arc light wires have greatly stimulated inventive ingenuity, but as yet without success.

Out of 72 patents that have been issued in this line, 53 of them have emanated from Philadelphia, New York, Boston, Brooklyn, Wilmington, Camden and Washington—all being in the immediate vicinity of the places where the operations were being conducted. The others were mostly from the general vicinity of Chicago.

Now, as to Chicago—much has been said of its system—a visit to Chicago satisfied me that its electric arc light industry was being strangled. A few blocks in the immediate heart of the city were using electric light very lavishly, but the area lighted is scarcely a half mile square. This small area is served from no less than nine separate plants, formerly belonging to as many companies, but now consolidated into one.

A letter under date of September 20th, from an officer of the Consolidated company, explains the situation there. He says: "We have had an enormous amount of trouble with our underground arc light circuits, averaging, I would say, for the last three months, one burn out every day. The expense of reconstruction and the losses in rebates have been enormous, and the annoyance to our customers more damaging still. Commencing in April last, we bought out some nine arc light plants in Chicago, and have proceeded to concentrate them into four main stations, burning about 1,100 lights; their owners had all been using underground conductors composed for the most part of okonite, kerite, Callender and underwriters' wire. Everyone of these insulators has failed constantly, the only thing that has held up at all is lead covered cable, and we have been driven to the great expense of taking out every foot of the old construction and substitute new lead covered cables throughout. This work is not yet done. Our people are confident that a large business awaits us here, but its development will depend entirely upon service. These lead circuits may fail much sooner than is anticipated, and it is almost certain that we shall be compelled to reduce the number of lights upon a circuit—a very difficult matter in a city like Chicago. Our conduit space is already filled along the main routes, and additional conduits will be necessary. The constant tearing up of the pavements for all kinds of purposes, makes our street department very unwilling to grant permits for laying additional conduits, and several times they have been refused altogether. I would say here, that arc light business in Chicago has developed entirely since the passage of the underground ordinance of 1881—the result has been the multiplication of small isolated plants and the formation of the nine small central station plants bought out by this company. None of these plants made any money. It was impossible for them to do so, operating underground and upon so small a scale. No streets have ever been lighted by electricity here, in fact the whole industry is in a very backward condition, and is likely to remain so, except in the most densely crowded portion of the city, unless some arrangement can be made with the city authorities for overhead wires. The city is trying an experiment of its own in lighting Chicago river, which will, I am confident, demonstrate the truth of the foregoing statement; and in the course of a year I hope that our city fathers will permit overhead lines, in many places where public convenience demands electric lights while underground construction would forbid it."

At Milwaukee, Wisconsin, three systems have been tried and abandoned—*i. e.*, a wooden truck plan, and tarred iron pipe and grooved wood. A fourth consisting of tile conduits with a heavily insulated but not lead covered cable had recently been introduced and is now being tested. The company doubts whether it will stand the trying spring season.

At Detroit, the Thomson-Houston Co. employed a cable of the most expensive and approved character in the Dorsett conduit, and the mechanical work was of the best quality.

While the cable was new the results were fair, though loss by seepage rendered it impossible to produce normal lights.

It was found impossible to operate telephone wires in the same or adjacent pipes. The company soon abandoned the system, and when its cable was removed it was found the insulation had so rotted or softened that considerable lengths of the wire in many places was stripped bare.

With the alternating system some wires have been undergrounded in Springfield, Mass., and in Denver, Colorado, and a small amount in Pittsburgh, but the voltage is only half that of the arc light systems, and even with this low voltage the lead covered cables have not been in use long enough to determine the question of their success.

The difficulty from explosions of gas has been met with many times at Chicago, New York, and elsewhere, as well as at Philadelphia, and seems insurmountable where gas is employed. At New York, men have been suffocated in the man-holes, and in the Western Union building the escape of gas from their conduits has been almost unbearable. At Detroit an explosion took place in October last, in the middle of the night in a fire-alarm conduit with close man-holes, and in which no wire had ever yet been placed. It doubtless occurred through the admixture of illuminating gas and sewer gas or other exhalations in proportions to explode spontaneously. The man-hole cover was thrown high into the air, the street torn up and the paving blocks scattered over a distance of eighty feet or more.

The problem of undergrounding arc light wires is by no means solved, but appears to-day to be further than ever from solution, owing to the utter failure of systems which apparently had all the elements to insure success. In this emergency municipal bodies must suit their action to the facts. To legislate arc light wires beneath the ground when no practical system is presented for accomplishing that end, is actually and literally to bury the system.

When a city is so sanguine of the soundness of its judgment, the remedy would seem to be for the city to provide conduits and the necessary cables, guarantee their success, and then compel lighting companies to rent their lines at a proper figure, or failing so to do to quit the field.

Summary action on any other basis is incompatible with that justice and equity, which it is the inherent right of every person

to demand and receive. Any other course is to discourage enterprise, and to ruthlessly impair or destroy capital invested in good faith.

The difficulty usually met with is a peculiar and unreasonable one. Municipal and legislative bodies view with suspicion the lighting companies, their officers, stockholders, and everybody connected with them. It seems to be assumed that because the companies make a certain showing of facts, the facts must necessarily be exactly the contrary, and they legislate accordingly. Thus, at Detroit, in opposition to letters produced by the lighting company, alleging repeated trials and failures at Washington, Philadelphia and Chicago, the then mayor, unquestionably in good faith, reported to the council, as the result of his personal investigation upon the spot, that no electric light wires had ever been buried in the city of Washington, a most glaring error, yet this was followed by a report of the committee, and unanimously adopted by the council, that underground systems of electric arc light wires were entirely practicable and were in successful use at Washington, New York and Philadelphia. At Cleveland recently, the strongest argument in the underground struggle advanced by the city, was that the wires of the Thomson-Houston Co., of Detroit, were operating underground in the Dorsett systems, whereas not a foot of arc light wire is underground in Detroit. To combat this unreasonable and unreasoning prejudice, the question whether any system yet discovered is practical and sufficient for the purpose, should be thoroughly and exhaustively examined, and an elaborate report made and published with full data upon which the conclusions are reached; this should be done by a board of competent and eminent men of national repute entirely disconnected from the electrical business, such as could be gathered from the scientific chairs of our largest colleges and polytechnic institutes, and it would rest with the interested companies of this association to contribute from their own funds or to influence the necessary contribution by the councils of their respective cities to pay the necessary expenses of such an inquiry.

UNDERGROUND CONDUCTORS FOR ELECTRIC CURRENTS.

BY JESSE M. SMITH.

THE question of underground conductors of electric currents is one which every person interested in electricity should study fairly and with a predetermination of solving.

It is not purely an electrical question, in fact, the electrical part of it is far overbalanced by the mechanical.

There is no difficulty in finding an excellent insulating material, but the difficulty lies in the holding of this insulator on the conductor.

Many substances are good insulators in dry places; some are good under water; some in damp places; and a few will stand acid and alkaline fumes and the ravages of sewer and illuminating gas, but how many will insulate under all these conditions and in addition be substantial enough to withstand the mechanical injuries to which they are exposed when buried under the streets of our large cities?

A few years ago wire wound around with a little cotton soaked in paraffine was thought sufficiently insulated until the insurance companies had a few losses, due of course to electricity, and then we had underwriters' wire.

The name of this wire has sold hundreds of tons of it, but that does not prevent its grounding a whole system when it comes in contact with the least moisture.

It, however, marks one state in the evolution of the perfect insulation.

There seems to be comparatively little difficulty in making a cable that will carry high potential currents when constantly submerged.

The conditions are substantially the same at all times. There are no alternate changes of moisture and dryness: no great changes of temperature; and very little of the destructive action of gases.

The conditions of the underground conductor are very different.

Here the conductor is dry, then wet; it is frozen, and again thawed; it is attacked by sewer gas, and the corroding action of the water leaching through the accumulated filth of the street; it is subject to the destructive action of the leaking gas and steam pipes, and finally, but not the less surely, to the ruthless "ditch digger."

These are certainly formidable obstacles, but a number of them have already been overcome, and the others must be.

Public opinion says the wires of all kinds must go underground, and electricians, engineers, and capitalists must find the means of doing it.

The question resolves itself into three parts.

1st. The electrical insulation of the conductor.

2d. The protection of the insulator from the effects of moisture and corrosion.

3d. The protection of both from mechanical injury.

The question of electrical insulation seems to me to be solved by at least six of the standard compounds now in daily use

The second part of the question is the most serious.

If any of the standard insulations can be enclosed so as to be protected from direct contact with moisture their chances of life are certainly improved, but if they can be hermetically sealed, they should be practically indestructible provided the casing is indestructible.

We single out as among the best materials from which to form such a casing—iron and lead.

Cast iron, underground, will last a great number of years, as shown by gas and water pipes, but it cannot be obtained in lengths much over 13 feet, and the numerous joints multiply the chances of leakage. The conductors must of necessity be drawn into the pipe after it is in place.

The conductor must be considerably smaller than the pipe, and therefore moisture will creep in between the two.

Wrought iron pipe if well coated with asphalt or some similar substance will last a long time.

It may be had in longer lengths than the cast pipe, and the joints are more easily and surely made.

If screw threaded joints are used the conductors must be drawn in, with the same objections as with the cast pipes. If the lengths of pipe are prepared with the conductors in them before laying, joints must be made in the conductor as well as in the casing, at short intervals.

Joints are the bane of electrical construction. From the dynamo to the lamp and return the current is forced to pass joints which frequently offer more resistance than 1,000 feet of wire.

At these joints the insulation, instead of being better than at other points of the conductor, is generally worse, and oftentimes none at all is found.

It is not strange that the current should seek an easier path home, and take to ground, rather than be forced through the accumulated resistance of all these joints.

I will venture to say that of all the failures of underground conductors, 90 per cent. are directly traceable to the joints, and for that reason it is desirable to have as few as possible.

The conductor may be obtained in, practically, any length, and the insulation may be put on continuously, but in order to have a continuous casing it must be formed of some soft and ductile metal which can be closed about the insulated conductor in the course of its manufacture.

Lead seems to be the only commercial metal that will meet these conditions, and there are objections even to it.

Lead is soft and easily punctured and offers little resistance to crushing or bending, and is attacked by rats.

On the other hand, the corrosive action of the earth has little effect upon it; while its pliable nature permits of its use in many places where iron pipe could not be used.

Being soft and ductile it can be brought into such close contact with the insulation as to prevent or at least retard the creeping of moisture between the insulation and casing.

It seems to me, therefore, that lead casing offers more advantages and less objection than any other form of protection to insulation as yet open to our use.

The third part of the question, viz.: the mechanical protection of the casing, and hence the conductor, is not so difficult a matter.

If an iron casing is used little or no protection is needed.

The pipe is strong enough in itself to withstand any ordinary abuse.

If lead is used, however, it should be kept from contact with sharp stones, bits of glass or metal, and have something about it to warn the "ditch-digger" before he strikes it with a pick.

An ordinary square wooden box is oftentimes sufficient.

If it does rot away it leaves a bed of soft mould.

The box may be made of white oak well creosoted, in which case it will last until the next generation finds something better.

If the underground conductor is to come into practical every-day use, it must be so constructed that it may be tapped at any point, as readily and with as much certainty as a water main is now tapped.

How many miles of lead water pipes are now buried in our streets?

They are not protected by boxes or conduits of any kind, yet it is comparatively rare that we hear of their failure.

If such pipes filled with water can be laid in the earth without protection, why can not a lead pipe filled solid full with copper and insulation be buried with even more success?

Good workmen can certainly be found who can cut a conductor, splice in a branch and solder it, replace the insulation, and finally wipe a joint on the lead casing with as much ease and certainty as a plumber can make a joint in a lead water pipe and have it stand 100 pounds pressure,

In a general system of distribution there are two classes of conductors, one which we may call through mains or feeders, and another service mains.

A number of through mains may be bunched together in a cable, under one casing, where they run in the same direction for considerable distances. These may be drawn into conduits, as they are not to be used between the main distributing points.

Service mains must, however, be so constructed that they may be tapped at any point, and that very readily.

Large sums of money have been spent in New York and elsewhere on conduits for electric conductors.

Are conduits necessary or desirable in electric lighting? Service wires are of no use whatever if placed within them unless man-holes are provided at every 100 feet. Through mains are certainly well protected when drawn into conduits, but at a great expense. No engineer would, I think, at this day, risk putting a conductor in any conduit which he would not be willing to trust under water or laid directly in the earth.

Why not take one half of the money which these conduits cost and use it in buying thicker lead casing and bury the conductor in the ground or in a common wooden box?

The underground conductor of the future, I believe, will be formed with a core of copper cable, thoroughly insulated by any of the standard and well tried compounds; protected by close fitting lead casing, thick enough to resist mechanical injury, and buried in the earth in such a manner that it may be tapped at any point. But where is the money coming from to pay for these conductors?

Whenever electric light plants are installed in a thoroughly mechanical and substantial manner, with due regard to the most economical production of power, so that the electric light is perfectly reliable and obtains public confidence, then the money will be forthcoming.

When capital enough is invested in electric lighting to enable it to cope with the vast sums which have been accumulating these many years in the gas industry, then we shall see our dynamos driven by the waste heat and refuse products of the gas works, and our houses will be heated by gas and lighted by electricity.

THE RELATION OF ELECTRIC LIGHTING TO FIRE INSURANCE.

BY S. E. BARTON.

In considering the relation between electric light and fire insurance interests, I must confine myself mainly to the situation in New England, because I am familiar with what has been and is now being done there, and I am quite as unfamiliar, except in a general way, with the relations that exist between the two interests outside of that small but lively quarter of our country.

In order that you who live away from New England may better understand what I may say as I proceed, it will be well for me to tell you briefly what kind of an insurance organization we have here.

The New England Insurance Exchange, which exercises a modest control over a part of the fire insurance matters within that territory (with the exception of the city of Boston and state of New Hampshire), is a body composed of the special agents, adjusters, traveling men or so-called "field-men," representing the various Stock Fire Insurance companies doing business there—some one hundred and fifty in number. These men mostly have their headquarters in Boston, which is verily a "Hub" in that respect. They are constantly skirmishing over the territory, individually or in squads of two or more, adjusting losses, and occasionally, through the co-operation of their local agents in the towns and cities, stealing good risks from each other or from some other competitor; but every Saturday finds a large majority of them back in Boston, where they convene in regular session and consider, with legislative dignity, any matter of common interest—electric lights included. They swap experience, swap yarns, swap anything for something better; consequently, they are a body of wonderful unanimity in any cause that promises common good to themselves and justice and fairness to others. They say to electric lights "burn," after our inspector has approved the manner in which you are installed and maintained; and as a consequence there are in New England to-day, not including Boston and New Hampshire, 13,944 arc and 157,848 incandescent lamps radiating their beautiful bright light where the feeble flicker of the gas jet and kerosene lamp could not penetrate. So concerted is the action of these men, that were they, by reason of any necessity, compelled to say that electric lights shall not burn, comparative darkness would once more reign supreme in that fair land; but while they continue to count upon their fingers the yearly fires caused by this modern illuminant, I think I can safely assure you that their dreaded power of extinguishment will not be exercised. I have made exceptions of the city of Boston and state of New Hampshire, the reasons for which are these: The former, in its fire insurance matters, is supervised by a similar organization to ours, known as the "Boston Underwriters' Union," which handles electric lights in the same manner as our exchange. The latter, through antagonistic and unfair legislation over two years ago, caused the absolute retirement from that state of every outside Stock Fire Insurance company, and they now manage that business themselves. By what light they work, we know not, but judging from their sad experiences of the past year, we are led to believe that they work by the unholy light of their own wicked ways.

I have described the character of our exchange principally to show the difference between it and most of the insurance organizations of our country, which are generally composed of officers of companies, or local or general agents in the large cities, between whom, by reason of their greater competitive relations, there exists a less amiable desire to harmoniously and successfully devise and carry out methods of improvement and mutual good. In the first year of our existence, some five years ago, we realized, after having paid considerable sums for losses caused by electric lights, that our interest demanded the inspection of all such apparatus by some person selected by ourselves, if we were to continue granting permits for the lights without charge. We were a year or two, in a sort of experimental way, in getting settled down to a perfect system of inspection, but the result of the last two years immediately preceding 1887, showed us, for the labor we had undertaken, a loss of less than eight thousand dollars from electric lighting in our territory. We had by that time not only given up all thought of making an extra charge for a permit to use your lights, as we do in many cases for kerosene oil, and in some instances for gas, but we were fast beginning to show our preference for your illuminant by granting reductions in our rates of premium. The year 1887 has shown us a loss record from your lights something less than any previous year, notwithstanding the great increase in your installations, and the spirit of recognition of your superiority in point of safety, has steadily gained ground, until, I am happy to predict, that before another month has passed the New England Insurance Exchange will have announced its favor in the form of a schedule of reduced rates which it purposes to make on certain classes of risks where the exclusive use of electric lights is guaranteed. I think that in this respect we will have fairly taken the lead.

A proposition to this end was made by the electric light committee of our exchange a year ago, but while we had for two years previous made an occasional reduction in rates, and have done so more generally during the past year, the time has not seemed ripe until now for an open announcement to that effect.

This feeling of preference for electric lights has been very gradual in gaining ground with us, and has reached a general recognition from the fact that the fires from that source have been few in number and the losses small in amount; and this favorable result has most assuredly been due to our perfect system of inspection. In this claim I am supported by the greatly increased number of fires that are reported as occurring in sections where insurance inspection does not prevail.

That there are in your method of lighting many inherent possibilities of causing combustion and loss of property thereby, I need not claim, because none of you would for a moment deny it; but what I do claim, and mean to persist in maintaining, is that there is no reasonable excuse for any fire to be caused by your apparatus, except in very rare cases where some unexpected and unavoidable accident may occur. It is quite possible for you to reduce the fire hazard of your system to the very lowest degree. It is quite *impossible* to do so with any other means of artificial lighting.

How can any care or control be exercised over the promiscuous use of kerosene lamps, while men, women and children, are handling them? What can prevent the innocent but agile cat from upsetting the lamp carelessly left in its path, as it is not infrequently accused of doing? Surely no insurance inspector, even with *his* ubiquitous habits, could prevent such catastrophes.

While greater care and a system of inspection could prevent many explosions in the gas system, they could not prevent combustible material from coming in contact with the open flame, neither in the dwelling, the store, nor the workshop; nor could they prevent an accidental escape of gas through a leak, or a burner carelessly left open, and in that event no amount of cautionary rules could deter the innocent occupants of the premises from going in search of the leak with an open light in their hands.

While our policies distinctly exclude damage caused by explosion, unless fire ensues, and then only cover the damage *by fire*, there is usually fire enough to "ring us in," and the drawing of the line between the explosion and the fire is usually disastrous to us.

Therefore I hold that, while no possible human foresight can prevent fires from the old methods of lighting, it is not only possible, but quite an easy matter, to prevent them in your case, if you set about it rightly.

If I were to presume to offer advice in the matter, it would be this: Where insurance inspection is already being practiced, combine among yourselves and support it by paying whatever is reasonable for carrying on the work in an intelligent and economical manner; also by helping them improve their rules and requirements from time to time as your experience develops new means of safety.

Where such work is *not* being performed, get together in the same manner, those of you who are operating in that field, and ask the insurance men to appoint an inspector; then submit your work to him, conform cheerfully to his reasonable requirements, and go to the public with his approval. The approval by insurance companies of any lighting, heating or power device is *necessary*. The public *wants* light, heat and power, but it *must have*

insurance, for on that the great commercial fabric of to-day depends for solidity.

By such inspection you will bring the fire hazard down to the minimum; you will largely increase the growing confidence of the public in your lights; you will rapidly clear away any lingering prejudice with insurance men against you, and in place of opposition that you may now occasionally meet with from them, you will readily obtain their fullest endorsement; more than that even, you will doubtless receive positive encouragement from them in the way of concessions in rates, in many cases.

The two interests should harmonize and work together to the greatest degree. You have in your system of artificial lighting great possibilities of reducing the enormous fire waste considerably; while we have, through our endorsement and encouragement, the power to largely increase your development; and the two together can give mankind more light and better light, and they need it.

I do not hold that you are deficient in any degree as to what does and what does not ensure safety in your work, but I think that you will agree that in the construction and maintenance of your equipment you are sometimes obliged to depend upon those who are not so proficient in their calling as they might be. The good insurance inspector, who gleans his knowledge and experience from all, helps you to educate and improve in usefulness those employed to whom you entrust your work. I refer particularly to the construction and dynamo men, and the trimmer —to the latter more particularly. If this functionary had possessed a knowledge of the possibilities of fire from the arc lamp, the losses from electric lighting in New England last year would have been too inconsiderable for mention.

Right here I wish to speak of the habit that sometimes possesses local companies—that of hiring inexperienced help because it is cheap. It is false economy, I think.

Competition, which is very great among you, drives you in some cases to lowering the standard of your material and work. It compels you to figure in every possible way to get a job. Nine of you may be honestly inclined to maintain the highest degree of perfection, but the tenth one outbids you all by figuring for cheap work. Careful and conscientious insurance inspection brings him up to the rack, or shuts him out, and we all profit thereby.

The question of insulation was referred to in a pointed and timely manner by our friend Haskins, a year ago, and his suggestions seem to have taken root in the east. Insulated wire is now the rule, rather than the exception, in those places where insulation is most needed, and painted wire has "lost its grip." The difference in the cost is too slight, and in point of efficiency and economy too great to allow the reform to languish.

The location of central stations seems to be receiving merited attention, but not to that extent which the good of the profession demands. In the past, the practice has been to secure power, especially in the smaller places, where it could be had the cheapest. without regard to permanency and surroundings. The result has been that you have gone into cramped quarters, with hazardous occupations on all sides, above and below you. You have got power by using boilers already being worked well up to the limit of safety, or you have set other boilers in the limited space at your disposal.

There have been fires and losses charged to you which you might have escaped by locating more wisely, and as a consequence, too many insurance men now look upon the electric light station as one of the hazardous risks.

Locate by yourselves as much as possible; build after modern fashions; do not spare brick walls and cement floors where they will add to your safety, and then you will get lower rates from Stock Fire Insurance companies or our "Mutual" friend, Woodbury, will provide for you.

There are in New England, as many of you are aware, a dozen or more good, strong Mutual Fire Insurance companies, known as the "Manufacturers' Mutuals." They confine their acceptances of risks to the largest and best manufacturing properties in New England and the middle states, and, to a limited extent, in the southern states and Dominion of Canada. Mr. C. J. H. Woodbury is one of the vice-presidents of the largest of these Mutual companies, and the recognized expert authority for them all. About five hundred of the large manufactories insured by them are lighted by electricity, either arc or incandescent, and very largely isolated plants. They have received the inspection of Mr. Woodbury, and the greater part of those in New England, that of Inspector Brophy, also. I take pleasure in quoting from a letter on the subject recently received by me from Mr. Woodbury. He says:—

"When electric lighting was first introduced it was the cause of a great many fires, there having been twenty-three fires from this source in the sixty-one mills using it in 1881 and 1882. By April, 1882, all the electric lighting plants in property which was insured by the Mutuals had been changed to conform to the rules for installation which I had prepared in December of the previous year, and since that time *we have not had a single fire from electric illumination. I do not know of* any fires caused by electric lights which did not owe their origin to a disregard of principles laid down in these rules as essential for safety."

I think that statement bears me out in my assumption as to the almost entire immunity from fires due to artificial lighting that is attainable by the use of your methods, and I ask no better support.

Mr. Ridlon has advanced some excellent ideas looking to better work, in point of safety, in construction and maintenance, —that of examination for fitness and qualification of the men who do this work, and the granting of certificates to them if found competent, the same as is done in the case of steam engineers. He would have the board of examiners composed of electrical and insurance experts. The absolutely impartial inspector is still needed to see that the "*tenth man*," of whom I have previously spoken, does not prosecute his nefarious work without a certificate; also to see that those *who hold certificates* are not intrusting their work to cheap men *who don't hold them*, or that the guileless trimmer is not falling into the habit of leaving the bottom off his arc lamps.

I would not occupy your time with technical suggestions, if, indeed, I had any to offer, because they had better be left to printed rules and inspectors; but it may interest you to know to what extent your business has prospered in New England.

The following figures are taken from our inspection records, and are probably about right. They are *inclusive* of Boston but *exclusive* of New Hampshire. For comparative purposes, I give them as they stood at the beginning of 1886 and also 1882.

NUMBER OF ARC LIGHT CENTRAL STATIONS.

	1886.	1888.
In Massachusetts....	26	45
" Rhode Island	5	8
" Connecticut	9	21
" Maine....................	4	14
" Vermont	None	5
Totals................	44	93

Increase of 1888 over 1886, 111 per cent.

CAPACITY OF ABOVE IN ARC LAMPS.

	1886.	1888.
In Massachusetts.......... (Including 2,168 in Boston in 1886 and 2,475 in 1888.)	3,693	7,305

" Vermont...............	None	475
Total........	24,120	68,598

Increase, 1888 over 1886, 184 per cent.

Total arc lamps, 1886, 6992; 1888, 16,419. Increase, 1888 over 1886, 135 per cent.

Total incandescent lamps, 1886, 33,720; 1888, 165,848. Increase, 1888 over 1886, 392 per cent.

Total arc and incandescent, 1886, 40,712; 1888, 182,267. Increase, 1888 over 1886, 348 per cent.

Those of you who know the ratio of increase in other sec-

tions of the country for the corresponding period, can judge if New England insurance supervision is a detriment to your business, or otherwise.

A whole year without any considerable fire loss in our country from electric lighting, would be a splendid record, but none too good for any of us to contemplate.

While such a result is far outside the bounds of probability, in the present condition of things, it is well inside the bounds of possibility. As well might we hope to revolve the earth from east to west as to hope for anything short of millions of dollars of fire loss annually from the old methods of illuminating by combustion,—the candles, the gas, and the kerosene oil flame, and the accompanying friction match.

INDEPENDENT ENGINES FOR INCANDESCENT STATIONS.

BY WM. LEE CHURCH.

COMMERCIAL success in incandescent lighting depends primarily on the continuous, cheap, uniform, and flexible generation of power.

The service of electric lighting differs from other forms of manufacture in requiring more horse-power per square foot of floor space; in requiring higher speeds; in demanding the power in larger units; in compelling a closer and more uniform regulation; and in calling for more rapid and constant extensions. It will be observed that these peculiarities require individual and special treatment in the generation and distribution of power; and engineering practice as determined in other lines of manufacture may be sadly at fault when applied to electric machines.

It has become an axiom among experienced station managers that "the money is made or lost between the coal shovel and the belt." In other words, other things being equal, the dividend earning capacity of a station is determined by its steam plant, to which the electric apparatus is to that extent in the nature of an accessory.

Incandescent lighting has not until recently made a brilliant record as an investment, and much of the disappointment is directly traceable to the culpable ignorance of the principles of steam engineering which has been displayed. A man who will not venture to cut himself a two dollar vest will not hesitate to exercise his amateur talents on a steam plant, upon the economical and reliable performance of which depends an investment of $1,000,000 and the public service of a city. A long and critical experience in this branch of industry has grounded the conviction that no incandescent station can hope to be financially successful under the ordinary conditions of competition unless based on independent dynamos belted direct from independent engines. Throughout this paper, therefore, we desire to keep constantly in view the opposite systems, namely, a station containing a given number of dynamos of two or three different capacities, each belted direct from high speed engines of corresponding rating; and, on the other hand, the same station with the dynamos driven from one or two slow speed engines, transmitting their power through a line of countershafting and pulleys. Having these pictures well in mind, we inquire:—"What are the essential requirements of a first-class steam plant in an incandescent electric light station?" Taking them up in the order of their importance, we unhesitatingly say;—first, and always foremost,

ABSOLUTE RELIABILITY FOR CONTINUOUS RUNNING.

The electric light company contracts to supply the demands of a diverse and exacting public, and that public expects to find its light on tap every moment in the year. Failure of service in ever so small a degree is palliated by no excuse. Complete reliability is the condition of popular confidence and patronage, without which all other economies and excellences go for nothing.

Again, electric lighting perhaps more than any other industry has its earnings directly affected by the shutting down of its power, since it sustains a direct financial loss for lights out, aside from loss of custom and reputation, not easily regained. Subdivided power reduces this risk to a minimum, and properly directed and applied obviates it altogether. In a station using 2,000 h. p., say, in the shape of two large engines, the loss of income in one night by the shutting down of one of these engines is equal to one-half the cost of an independent engine on the subdivided plan. In other words, as tersely expressed by a manager of experience, a company might better for peace of mind, reputation, and cash balance on the books, throw a 60 h. p. engine into the scrap pile than to shut down the station one hour. The service of electric lighting is similar to the editing of a daily paper in that lost time can never be regained. Most industries can make up lost time by working overtime and by pushing their business in various ways, but in electric lighting

> "The mill will never grind with the water
> that has passed."

Passing from argument to instance, we cite the recent experience of one of the largest stations in the country, operating in the neighborhood of 20,000 lights. This station as originally planned was driven from a pair of Corliss engines, each having a cylinder 28″ in diameter by 48″ stroke, and belting to a countershaft 4¼″ in diameter by about 50′ in length. From this countershaft are driven five dynamos, having an aggregate capacity of 6,000 16 c. p. lamps. Clutch pulleys 8″ in diameter are the means of disconnecting the dynamos when not in service, with similar clutch pulleys for the exciters. The remaining dynamos in the station are each 2,500 lights capacity, and each are driven by a 200 h. p. independent engine, belted direct. Recently in the middle of the heavy run of the evening, an accident occurred necessitating the immediate shutting down of the 6,000 lights, besides doing considerable damage, and involving danger to the employés. It happened that one of the engines with its dynamo was immediately available, and was started within two or three minutes, so as to take up a portion of the load of the large engine. In the same station, at a subsequent time, a key became loose on the valve gear of the engine, necessitating another stop for several minutes. On still a third occasion the crank pin became uncomfortably hot, and was carried through the run only at a great risk and labor. Illustration might be multiplied, but this is used as one among many of the almost evident facts that no electric light station can afford to hang its whole business upon any one source of motive power, particularly when that motive power is distributed through the complex mechanism of countershafting, involving risk of hot bearings, broken pulleys, defective frictions, and what not, any one of which may shut down the whole station. Had these same dynamos been each belted direct from an independent engine the accidents above enumerated could not have occurred in the nature of the case. We do not assume to say but that accidents of some nature are due in any piece of mechanism, but the division of power and generating capacity into comparatively small units, each independent of all the others, affords a practical means of distributing the danger, so that it is essentially nil in its effects. That is to say, had a stoppage of any one independent engine in a similar instance occurred from any cause, the other engines with their dynamos would easily have distributed the load for a short time, without any disturbance or danger whatever, and the service would have been uninterrupted while the repairs were being made or the difficulties remedied.

It has been incidentally remarked in another paper that independent engines afford a safeguard against danger from short-circuits, inasmuch as the current due to the short-circuit will overload an independent engine and slow it down, thus giving warning of the danger. If the dynamo is driven from a single large engine, the motive power will not respond to the short-circuit until it becomes equal to the full capacity of all the connected dynamos, plus the range of power in the engine. Practically, therefore, a single slow speed engine will not feel the short-circuit, but will pull it through until something burns away.

That merit of the steam plant which is most obvious, and which appeals most strongly to the electric light company is, *economy of fuel.*

The advocates of large slow speed engines rely upon the supposed superior fuel economy of this type as the sole offset to its obvious disadvantages. All managers unhesitatingly admit the superiority of transmitting the power directly and without loss from the engines to the dynamos, and more or less readily concede that in its performance the high speed engine will equal the running qualities and durability of the slow speed engine. If with this, say they, we could get the steam efficiency of the Corliss type of engine, no man would hesitate to decide in favor of the convenient, compact, and independent small engine. We take the question at once by the beard, and desire to state that of two incandescent stations operating under ordinary circumstances, and otherwise equal, except only in their power and transmission, that one which has independent direct belted engines will show in its monthly report sheet, not a small amount, but from one-quarter to one-third less coal per lamp hour, than the station driven from a single engine through countershafting, both types of engines being non-condensing. We go yet further, and state that independent non-condensing engines under certain conditions will about equal in economy an equivalent slow speed condensing engine. This is a fact so incontrovertible when actually and candidly investigated, that we do not propose here to demonstrate but merely to illustrate it.

We now submit to the prompt inquiry:—"Will not a high speed engine use more coal per horse-power than a Corliss engine?" Yes. "How much more?" Size for size and load for load not over 10 to 20 per cent. Score 10 per cent. against the high speed engine, and again ask:—"Will not several small engines use more steam than one equivalent large engine even of the same type?" Yes. "How much more?" Load for load possibly another 10 per cent. Score 20 per cent. against the high speed engine, and again ask:—"How an admitted loss of one pound of coal in every five can be reconciled with the statement of a monthly saving of 25 to 30 per cent. in favor of independent engines?" Answer: Simply because we have to deal with conditions as they exist in fact, and not as we assume them to exist.

The reason why independent engines can overcome their moderate lack of initial economy, and pass a large percentage of actual economy to their credit, are mainly two. First,—The use

of a countershaft implies power to run it. Indicator diagrams show that the dead load of such a plant varies from 12 to 20 per cent. of the gross horse-power under full load when in ordinarily good condition, and not infrequently rises to 30 per cent. and over with badly lined shaftings and badly drawing belts. Moreover, it must be borne in mind that the dead load is nearly a constant quantity, and if it amounts to 20 per cent. of the full load, it will under partial load equal and even exceed the net power transmitted to the dynamos. It may easily happen, every night in every station thus powered, that from midnight to morning two to three horse-powers are expended in the cylinder for each effective horse-power recovered at the dynamo pulley. Thus by one stroke and by a single item is the conceded advantage

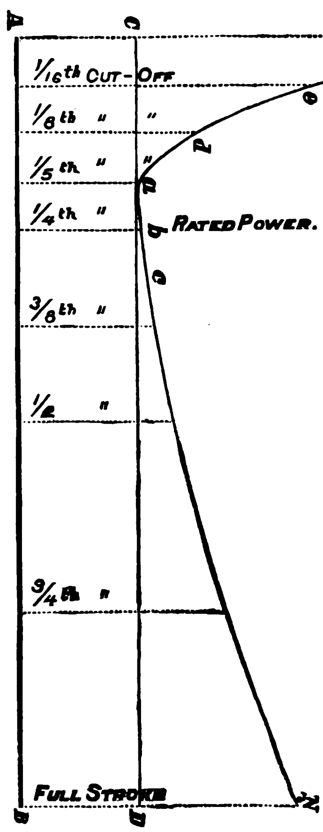

FIG. 1.

of the larger engines, reckoned in coal per horse-power, practically swept away, and large and small engines left standing on an equal footing, prepared to submit to the still more searching question :—"What is the cost from hour to hour of the power actually expended in meeting the fluctuation of the load?"

To consider for a moment some abstract facts in steam engineering, we must note that the steam engine develops its maximum economy (*i. e.*, minimum consumption) only over a limited range of its power. Under normal conditions of pressure, say 80 to 100 pounds in the boiler, this minimum consumption is found only between the points of 1–5 and 1–4 cut off, say from *a* to *b*, figure 1, at which latter point all engines are now rated. At its rated power, therefore, the single large engines of the Corliss type will consume as little as 26 to 28 pounds of water (steam) actually fed to the boilers per indicated horse-power per hour, and if the economy were not affected by the load we could represent the rate of consumption by the straight line CD. If overloaded, however, the rate of water consumption rises as shown on the right hand portion of the diagram, in which the horizontal distances represent the cut-off, and the vertical denominates the actual points of water consumption ; the curve, therefore, being a curve of efficiency at varying loads. It will now be particularly noted that whereas the line rises for an overload, it also rises for an underload, and very much more rapidly. This is well understood to be partly from excessive condensation due to over expansion, and partly from the greater percentage of leakage under short cut-offs. Considering figure 1 to represent the actual performance of a 400 h. p. engine at varying points of cut-off, it will be seen that the engine will be at its best only over a limited range, from *a* to *c*, or, say, from 325 to 450 h. p. An overload is, of course, mechanically injurious, which limits the possibilities in that direction. As the load falls off below 1-5 cut-off the steam rate increases in an enormous ratio, so that at 200 h. p. the engine is using 50 per cent. more than its normal rate :—*i. e.*, at 200 h. p. it is actually using the gross amount of steam which would give 300 h. p. if used in a 300 h. p. engine. At 100 h. p, the waste is fully 100 per cent., and the steam used should develop not 100 h. p., but 200 h. p., if used in a 200 h. p. engine. It must be borne in mind that the diagram is plotted from observation, and is not a diagram of theoretical deductions.

It now remains to determine if the conditions actually obtaining in electric lighting stations are such as will enable a single large engine to develop its normal economy ; and if not, then are they such as will enable the smaller independent engine, with a lesser initial economy, to reach a better gross result under the inevitable conditions as they are found to exist.

The typical daily chart of amperes delivered from an incandescent station of, say, 4,500 lights, is shown in figure 2, of course with variations in different stations, but always of the same general character. The chart is assumed to cover a winter night's run, commencing at 4 P. M., and shutting down at 8 A. M. The heavy irregular line, A B, represents the fluctuation of the actual load, such as would be determined by indicating a series of independent engines, and the area enclosed between it and the base line MN, may be denominated the net power required. The fine irregular line, CD, encloses the gross load when driven by a single large engine, being equivalent to the net load plus the friction of the shafting and pulleys required in transmission. The irregular band lying between AB and CD, therefore, represents the dead load, which is a net loss, due to the friction of shafting.

But, as shown above, this is not the full measure of the loss. We have already seen in figure 1 that an excessive underload requires a *relative* amount of steam which would be adequate to produce a much greater maximum efficiency. Combining the two diagrams, therefore, we would find a third dotted line, EF, which would clearly represent the actual steam consumption required to secure the net work, AB. The irregular band, therefore between AB and EF, represents the total loss expressed in coal. In other words, the entire area, EF, represents the lamps which should be got for the steam expended, whereas, EFMN, represents the lamps actually got for the steam expended. The loss involved is practically 50 per cent. of the total fuel in the whole night's run, which corresponds to observed results in stations

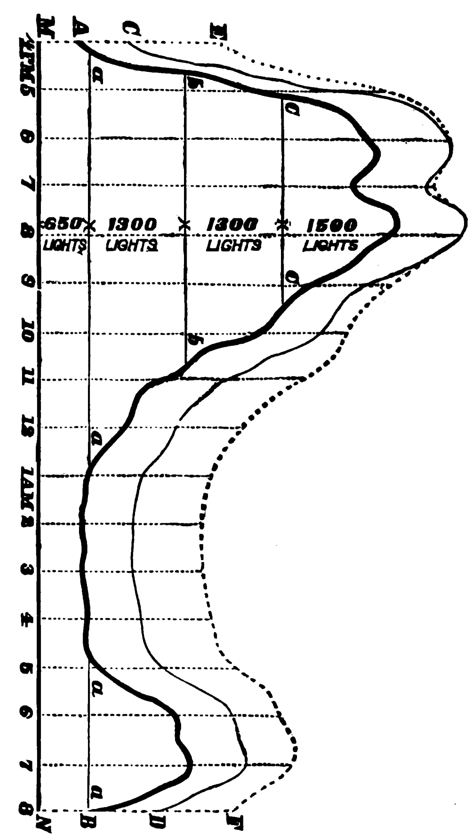

FIG. 2.

whose fluctuations of load are about as indicated. Of course, there are stations in which the net load averages more uniform than that shown, and a better proportionate result would, therefore, be expected from the single large engine with countershafting. We believe it safe to say, however, that there is no incandescent station which will get a load so constant as to secure the economy from a single engine equal to that which can be realized from subdivided power.

We now contrast the performance of independent engines in the same station. The lower narrow band between the lines MN and *aa*, represents the smallest dynamo, or successive loads

of 1,300 lights each. At starting time, therefore, a 60 h. p. engine with its 650 light dynamo is opened, and run continuously until shutting down in the morning. It will be noted that while running, the load on this engine is practically constant and at the point of maximum efficiency. In 10 minutes after starting, the load rapidly increasing, it becomes necessary to start the second 125 h. p. engine with its 1,300 light dynamo, which engine, again, runs on its full and most efficient load, as indicated between the lines *aa*, *bb*. This engine is stopped at 12.45, making another short run in the morning, and is, therefore, running to disadvantage for about an hour. At 4.40 the increase of lights calls for the third engine with its dynamo, which in turn runs until 10.45, and is then stopped. The point to be clearly understood as vital to the whole economic question, is, that each engine while running is loaded to its best efficiency, runs only so long as its load is called for, then stops altogether, and with it all consumption of steam, leakage, radiation, wear and tear, and loss of every nature. Ample time is given to inspect the engine and dynamo if necessary, and the system as a whole develops the last possibilities of commercial efficiency.

The above diagram practically represents the performance of two stations which we once had the privilege of comparing, both of which were of practically the same size and both constructed on the same electrical basis. We were by courtesy put in possession of the monthly reports from both these stations, which showed a ratio between the pounds of coal per ampere hour of 70 to 126 in favor of the station driven by independent engines. A station whose motive power is one or two large engines, therefore finds itself in a position of earning money between starting time and 10 o'clock, and spending it again between 10 o'clock and morning.

We have thus endeavored to make it clear in the above illustrations that the rated economy of the two types of engines is but a small part of the consideration, and cuts practically no figure whatever in actual practice under the condition imposed by the nature of incandescent service.

If any one is now unthinking enough to inquire :—Why not use a number of small Corliss engines in place of high speed engines, if it is admitted that the Corliss type is the more economical of the two?—we would answer, briefly :—First, small Corliss engines are not as economical as small single valve engines, the percentage of leakage due to the four valves and slower speed being much greater. Second, small engines of the Corliss type run necessarily at so slow a speed as to preclude the possibility of direct belting, and to involve full lines of countershafting, with their attendant cost and wast of power ;—Third, the first cost of small slow speed engines is very greatly in excess of that of high speed engines for the same power. We think no one has ever seriously considered, however, the adoption of small independent slow speed engines.

Next in importance to reliability and economy is *uniformity, delicacy and continuity of regulation.*

There is much misapprehension regarding the matter of regulation in engines used for electric lighting. Let us, therefore, ask :—What is good regulation? Good regulation implies, as a matter of course, reasonably small variation in speed, reckoned in R. P. M., between the engine fully loaded and the engine running light. Claims are made that such and such engines regulate to two per cent., one per cent., and even one-half of one per cent., under variations of load. Now, it should be clearly understood once for all, that any decent automatic engine controlled by a shaft governor can be so adjusted as to regulate, not merely to two per cent., or one per cent., but to actually pass the point of exact regulation and run faster under load than when light. So far as regulation in terms of R. P. M. is concerned, one per cent., or two per cent. regulation is sufficiently close for all ordinary purposes.

Second.—The most important consideration in the regulation of engines in incandescent stations is not their variation from minute to minute, but *from stroke to stroke.* An engine may make 300 turns per minute, counting for each successive minute of the hour, and yet may at any given instant be running sensibly above or below this speed, in the effort to meet a momentary fluctuation of load. We say every engine may do this, and we have observed that most engines do do this frequently, the difficulty being, not a matter of the construction of the governor, but purely a question of lubrication. A perfect governor is one which will maintain the speed, not at an *average* of 300 R. P. M., but at the *rate* of 300 R. P. M. for each and every stroke. Any properly constructed governor will retain the average of regulation to which it is set, but it can only secure instantaneous regulation when friction is practically eliminated. It has been our experience that nothing but a complete bathing of the governor in oil will practically accomplish this purpose.

Incandescent lamps require a regulation more delicate, perhaps, than any other industry. Any departure in regulation from stroke to stroke gives a variation of E. M. F., which is speedily destructive to the life of the lamp, that item which, next to fuel economy, is the heaviest tax. The injury is done during the period of acceleration immediately following the change of load, which period is the time between the change of load and the movement of the governor, and this in turn is proportional to the friction. It is obvious that if friction were annihilated the acceleration would be also nil, and the speed, and consequently the E. M. F., would never vary.

Third.—Under the extremely long runs now imposed by electric light service, continuity of good regulation is essential. That is to say, a governor which will regulate when well oiled will fail to regulate when its pins and bearings, being inaccessible under motion, have become dry during a long run.

As to the nicety of regulation obtainable from a slow speed engine, there is no comparison possible. We have already shown that it is not permissible for an electric light engine to vary its speed even from stroke to stroke. All observers know that it is frequently quite possible to count the revolutions of a slow speed engine, particularly when heavily loaded, by the pulsations in the lamps at a distance from the station. A slow speed engine, unless excessive in its fly-wheel capacity, will imperceptibly slacken in passing its centres, and this variation not visible on the engine. becomes a sensible and dangerous variation when multiplied to the speed of the dynamo. The fluctuations of the needle of two voltmeters respectively registering from a high speed and slow speed engine will give abundant evidence on this point.

FLEXIBILITY.

The characteristic of flexibility in electric light stations is one which is frequently overlooked until experience, except in stations where the lowest dynamos is small enough for the minimum unit, demonstrates its desirability. To secure the best possibilities in this direction, it is necessary to use dynamos of two or three different sizes, each being driven direct from its independent engine. The plant being thus divided into independent units of different sizes any variation of demand, either in the total load, or in the load required for different circuits, can be conveniently met. Owing to local causes, the load of a station is not necessarily the same from day to day. It is obvious that a plant in which all the dynamos are hung upon one, or at most two, engines, is essentially rigid in its control of circumstances. whereas a station planned as above indicated, is to the last degree flexible in meeting any variation of load to whatever degree it may occur. All this has a direct bearing both on economy of fuel and incidentals of operation.

We would not wish to imply that the smallest unit in every station should necessarily be the smallest unit as determined by the minimum load existing for any considerable time during the day. This minimum load in the majority of medium sized stations will represent about one-eighth to one-sixth the generating capacity of the station. That is to say, a station of 4,000 lights capacity should have one dynamo at least as small as 650 lights. Beyond this it is, perhaps, advisable that the units be uniform for the sake of interchangeability of parts. The whole question of units of generation must be considered, not in the light of any one rule, but under all the circumstances of each particular case.

MAINTENANCE OF PLANT.

The maintenance account of a plant often defeats dividends. In the use of countershafting an entirely new factor of expense is introduced, pertaining to the shafting, bearings, pulleys, clutch pulleys, belts, etc.

Each bearing of the countershafting will consume oil to the value of at least five dollars per annum, and any considerable amount of shafting involves the pay of an extra oiler to properly care for it. Regarding the two types of engines under discussion, it is undoubtedly true that the maintenance of the high speed engine will be fully as low as of an equal horse-power in slow speeds, as to its direct expense, without taking into account the time lost in repairs. Nearly all the high speed engines are made to gauge with more or less reference to interchangeability of parts. Repairs in consequence are furnished at a minimum of cost, and the parts being light and readily handled, the engine can be stripped, overhauled, and connected up, without the employment of an extra force of men or the necessity for heavy handling. In referring to high speed engines, we, of course, only speak of those which are carefully and understandingly designed for the work put upon them. That is, we wish to draw a sharp distinction between high speed engines and engines speeded high.

The one danger of high speed engines arises from the possibility of charging the cylinder with water which cannot be quickly enough relieved through the valve at the speed at which the piston travels. The fact that no engineer justly entitled to the name should ever allow an accident of this nature to happen, does not in the public mind shift the responsibility from the maker of the engine. Spring relief valves have now been brought to a state of perfection which leaves little to be desired, when the engine is of a type permitting their use.

SPACE OCCUPIED.

This is one of the minor considerations which in certain locations becomes of considerable importance. Not infrequently electric light stations are located near the business portion of the city, where real estate is valuable, and taxes correspondingly

high; and space counts heavily in the capitalized investment. Again, a large building obviously increases the investment, particularly when a building to carry heavy lines of shafting at high speeds must be of unusually massive construction. It needs no illustration to show that independent engines by doing away with the space occupied with countershafting and belts, under the least distance between centres which can be justified, require materially less space per horse-power than any form of non-subdivided power. This is particularly the case where the dynamos are placed on the second floor, over the engine room.

Moreover, the cramped space in which the single engine must develop and distribute its power is against its satisfactory performance. The fact is generally overlooked in drawing comparisons, that a single large engine in an ordinary manufacturing establishment, such as a cotton mill, has in the nature of the case a wide space in which to transmit its power from the slow motions of the engines up to the high speed of the spindles. This means that ample space is given to bring the speed by gradual accelerations, through easy moving shafting of substantial nature, up to a moderately high intermediate speed, and then distribute it to the spindles in small quantities by means of simple, light, fast running devices. In the dynamo room, on the contrary, the space is cramped to the last degree, and the slow running engine must *in short range*, multiply its power to high velocities, and transmit its speed in large units to the dynamos. The whole system of transmission becomes rigid and ineffective, and the loss consequent upon friction, and risk to employés, and the magnitude of disaster when any occurs, are such as in themselves to overbalance all the economy which the most enthusiastic advocates of slow speed engines attribute to them.

EXTENSION OF PLANT.

An electric light station, unlike most other industries, is usually of very rapid and persistent growth, to an extent which is not generally foreseen in the original calculations. The use of independent engines lends itself readily to indefinite extension. The power and dynamos both being divided into like units, each independent of all the others, extension becomes merely a question of more units, without any special preparation in the plan. On the other hand, the slow speed engine with countershafting is necessarily in large units, and to that extent fails to meet the requirements of a gradual increase. The use of the large engine involves an outlay disproportionate to the immediate returns from the first increase as ordinarily provided for, and it necessitates also the operation of the moderately increased plant at a great disadvantage on account of the underload involved, as already explained. The practical operator will readily see the force of this important advantage on the side of the independent engine.

FIRST COST OF PLANT.

This consideration, although really of the least importance among those enumerated, is distinctly on the side of subdivided power. The price of high speed engines per horse-power is now fully as low, and generally lower, than that of slow speed engines. Cost of foundations is materially less, as is also cost of erection and handling for repairs. There then comes into the question the clear saving of all the money invested in countershafting, pulley blocks, heavy belting, clutch pulleys, receiving pulleys, and similar devices. In the station to which we referred above the extra transmitting devices necessitated the investment of a sum not less than $6,500.

The price thus expended for worse than useless machinery would be sufficient to purchase practically 500 h. p. of independent engines, adequate to generate 6,000 lamps, showing a net earning capacity of at least $18,000 per annum.

When we contrast this with the net losses due to the system of concentrated power, as above discussed, it leaves no room for argument as to the advantage of independent engines in electric light work.

HOW CAN WE PROTECT OUR WATCHES AGAINST THE INFLUENCE OF MAGNETISM?

BY DR. P. LANGE.

I HAVE been invited to deliver to this convention an address on the influence of electric currents upon small magnetic matter. I can comply with this request in no better way, perhaps, than to devote myself especially to the discussion of this most subtle influence as applied in particular to the delicate mechanism of our watches. Every man among us has doubtless been often impressed with the idea that absolute accuracy is the most desirable quality a time-piece can possess; that reliability is most essential to render efficient a guide so frequently consulted as the watch. You will therefore acknowledge the real importance of the question as to how we can best protect our time-pieces from the influences of a magnetism that must render them inaccurate and unreliable. Since the introduction of powerful dynamos has taken place in large electrical establishments, and in the many buildings supplied with independent and separate lighting plants, it has become evident that the watches carried by persons coming in proximity to the dynamos (whether such persons be constantly employed near the dynamos, or only visitors to the works, it matters not) are very likely to become magnetized. Once under the influence of magnetism, the time-pieces must very soon show the effects of it, by either losing or gaining time, or stopping altogether; and the cause thereof is such, from its very nature, as would be liable to puzzle an expert watchmaker to remove. The advent of electricity in its modern and manifold branches of utility has forced upon us the importance of this question: How can we prevent this magnetism from gaining a damaging influence upon our watches? or, if not prevented, how can we best and most speedily repair the damage done?

Let us not look upon the question lightly, but rather in all earnestness. Let us bear in mind that, while the powerful dynamo in the engine room, in the manufactory, the business house or the ocean steamship sends forth its currents through many lines to furnish light or power, it sends forth also a very different influence, and one that makes mischief with the watch carried by the engineer or electrician, the visitor to the works, or the captain, or the pilot who may happen to approach for a moment within the influence of such a dynamo. Let us not forget that, in the latter event, serious results may follow, for, by the captain's chronometer, in conjunction with the compass, the great ship is sailed. We should bear in mind that, in the manufacture of our best watches, the object of the maker is to confine in the smallest space possible the greatest strength and durability. In order to accomplish this object, he finds it necessary to use, for the principal parts of the watch, hardened steel, a material decidedly susceptible to the influences of magnetism. The hair spring and the balance wheel—vital parts of the watch—are thus frequently constructed; and even though the balance be made of a combination of metals, the steel in the little points on the wheel may be attracted to the little steel screws necessary to perfect firmness in the larger mechanism of the watch, for these screws may be readily charged with magnetism of sufficient force to be long retained and to exert a continual influence over the other magnetic matter. This escapement wheel, likewise of steel if durability be desired, becomes easily magnetized also, and its movement is seriously retarded. Then the hair-spring, with its delicate coils close together, may be so polarized that the coils on the side next to the nearest steel screw will all adhere to each other and play havoc with the motion of the watch.

Thus our very best time-pieces are most susceptible to the influence, which may, and often does, retard them to the extent of several hours a day.

In my work as an investigator of this subject, which has extended over a period of several months, I have formed three separate solutions of the problem: First, to have the watch made of material that cannot be magnetized; second, to inclose the works in an iron case, so as to shield the vital parts of the watch, and third, to apply efficient means to demagnetize the watch that has not been favored with the safeguards.

With regard to the first solution, I have had occasion to experimentally test its efficiency. I have applied the most complete magnetic tests to watches made by a well-known watch company, which were claimed to be perfectly free from all magnetic influences. The hair-spring and balance wheel of these watches are made of palladium. I have no hesitation in saying, after subjecting these watches to the strongest magnetic influences in the Westinghouse Electric Works, that their claim to recognition as non-magnetic time-pieces is fully sustained. I have had one of these watches perfectly timed to run with another, and subjected the two to opposite extremes as regards magnetism, yet discovered no deviation in their time keeping. The one was wholly free from the magnet influence; the other was running at a point between the pole-pieces of a most powerful magnet. I have watched both of them closely for weeks, without being able to detect any difference in their time.

Taking the hair-spring and balance wheel from a watch, I have placed them upon a little cork float in the water, and then approached them with a most powerful magnet, without being able to detect the slightest motion of the little float or its burden; whereas the ordinary steel hair-spring and balance wheel, subjected to a similar test, were so strongly attached that they not only moved the cork float but jumped from it to the magnet instantly.

While it is true that the screws and a large portion of the other mechanism in these watches is made of steel, yet all the delicate movements in the work are so entirely non-magnetic that, although the steel parts should be charged with magnetism to the highest degree, there would be no perceptible effect exerted upon the running of the watch.

Concerning the second solution of the problem, that is, shielding a steel watch against magnetic influences by inclosing it in an iron case, I would say that I have not personally experimented with them: but acquaintances of mine, entirely competent to do so, have given me an excellent idea as to what such watches are capable of. Watches, in such cases, have been very successful in resisting the ordinary influences of the dynamo rooms. But I would not advise that they be exposed to the influence of very

strong fields, because, in that case, they would be magnetized and lose time.

Now, for the third solution of the problem. Since it is true that comparatively few non-magnetic watches are in use, and that there are a great many of the ordinary watches with steel works, the question comes up, naturally: How can we best demagnetize the watches if they have become injuriously magnetized?

An old way of doing this was in placing the magnetized timepiece in close proximity to a dynamo, then revolving the watch rapidly by means of some mechanism and slowly removing it from the magnetic influence. This is a very unreliable cure at best, and, in many instances, quite ineffective. A much better method has presented itself to me. I had occasion, recently while constructing instruments for the alternating current, to observe some facts in connection with this kind of current and its peculiarities, which were suggested to me as being entirely available for use in the process of demagnetizing watches. In sending an alternating current through a solenoid, without breaking the circuit in the latter, I found that the steel core had lost its magnetism entirely. Magnetizing the core as strongly as I might before this operation, it would be, as I discovered, entirely demagnetized after submission to the process described. Then I found the same proposition to be equally true as applied to a whole handful of steel particles. They might adhere to each other ever so strongly before the operation; but if I endeavored to pick one of them out of the solenoid with the circuit undisturbed, the steel particle would come out entirely alone, wholly demagnetized and free from attraction to the others. Then I tried a watch whose steel pieces were thoroughly charged with magnetism, and I found that the same process exerted the same effect upon the watch as upon the steel core or upon the many particles of adhering steel. It was utterly demagnetized in all its parts—perfectly cured of its magnetic ailment. It would be unsafe to bring such a perfectly restored watch within the influence of magnetism, unless the owner should be desirous of again resorting to the still reliable process described. The solenoid need not be described to electricians. It is a very simple contrivance filled almost to the top with soft iron wire, leaving just room enough at the top, if designed for the purpose described, to allow the insertion and removal of the watch in the manner noted. Any person can apply the test successfully, and, if it be in a jeweler's store or any other place lighted by incandescent lamps supplied for alternating current, the person need only remove the lamp from its socket, insert an attachment plug in its stead, connecting the current with such a solenoid, dip the watch in the hollow end of the solenoid, and, after leaving it in there awhile, remove it without disturbing the circuit. In this way a perfect cure for magnetized watches might be applied in any store, factory, or other establishment having alternating incandescent lighting plant. In conclusion, I have only to say that the first solution of the problem described above, namely, that of getting perfectly non-magnetic watches, is the best and safest one for those whose time-pieces are liable to be subjected to magnetic influences. I may also add that the third method or cure described demonstrates the wonderful resources of the alternating system of electricity, which, though it may work damage like other systems, has yet within its own qualities a perfect curative power, which cannot be claimed for the continuous or direct current.

THE ENERGY OF ALTERNATING CURRENTS.

BY O. B. SHALLENBERGER.

The adoption of the alternating current for electric lighting has introduced a number of questions in regard to its measurement which have an important practical bearing, since they involve the subject of the relative efficiency of the direct and alternating systems; and for this reason, perhaps, a few words on this subject may not be amiss.

It is not proposed to enter into a mathematical discussion, but rather to offer a few illustrations and examples which will assist in a general understanding on the subject, and at the same time prove the uncertainty of the well-known rules for direct currents, when generally applied to alternating currents. Under certain well defined conditions such methods may be employed without sensible error, and fortunately for the electric lighting industry, these conditions are naturally present in the exact kind of apparatus necessary for the simple and economical distribution of the alternating current.

In estimating the amount of energy expended in a circuit traversed by a direct or continuous current we are accustomed to base the calculation on measurements of the difference of potential between the two points of the circuit in question, and at the same time, the current traversing that circuit. The product of these two quantities, as is well-known, gives a correct measure of the energy of the circuit expressed in watts. This method may or may not be applicable to alternating currents, the distinction depending upon the presence or absence of self-induction in the circuit. In the case of a straight copper wire going out from the source of current and turned back on itself in close proximity, it may be assumed that self-induction is practically absent, and hence no sensible error would be involved in taking the product of the difference of potential between any two points, as measured on a Cardew voltmeter, and the current traversing that portion of the circuit as determined by a Siemens dynamometer, and then using these two factors in the product which represents the amount of the work done. This would give a correct result; but the introduction of a coil of wire wound in one direction, especially when it surrounds an iron core greatly modifies the conditions, and causes an error the amount of which is dependent on the form and size of the coil. The reason for this is that an additional element of self-induction has been introduced, with consequent retardation of the phases of current. This simply means that, as the difference of potential alternately rises and falls and reverses its polarity, the corresponding fluctuations of current do not occur at corresponding instance of time. The want of synchronism may be of any amount between zero and a quarter of a complete wave length. When there is no self-induction present in the circuit, there is no displacement, but a departure from this relative position may be produced by introducing self-induction into the circuit, and to a point which may theoretically cause the waves of the current to lag a quarter of one complete alternation behind the waves of the electromotive force, although it is impossible to realize this amount in practice.

Let us inquire now what is the effect of this displacement on the amount of energy expended in the circuit; but as a preliminary step it will be well to examine the case of a secondary battery which is being charged from a suitable direct current generator. Suppose first, that current is supplied from the generator with a sufficient electromotive force to overcome the counter electromotive force of the cells and produce a certain flow of current. We may introduce into the circuit a suitable ammeter to determine its amount, and connect across the circuit a voltmeter, and by the product of the indications of these two instruments we obtain a result which shows the expenditure of energy at that time. But if, later in the process of charging, the speed of the generator is reduced to such a point that the counter electromotive force of the battery is sufficient to overcome the electromotive force of the generator and cause a flow of current in the opposite direction, it is well understood that the battery would no longer be charging, but would be running the dynamo as a motor, and consequently expending energy upon it. If the resistances of the armature and battery are low, the readings of the voltmeter and the ammeter might be exactly the same as in the former case, and the product of these two factors would of course show the same amount of work done. In the absence of any other information than the readings of these instruments it would be impossible to judge whether work was being done by the generator on the battery or by the battery on the generator. Another element requires consideration, and that is the direction of the current as related to the difference of potential across the circuit. Referring to diagram 1, a generator is shown at G, supplying current to charge a battery at L. Let it be assumed that the electromotive force of the generator is in such a direction as to make the upper conductor positive, with relation to the lower. Calling this a positive electromotive force, a current in the direction of the full arrow would be positive, and one in the direction of the dotted arrow would be negative. Whenever the generator is doing work on the battery the current flows from the positive to the negative conductor through the battery, or in the direction in which the generator tends to deliver the current. If we had called the electromotive force of the generator negative, this would be a negative current. We can assume either, but in each case the current and electromotive force have the same sign. When, however, the electromotive force of the generator falls sufficiently to allow that of the battery to overcome it and send a current in the opposite direction, as shown by the dotted arrow, the conditions are reversed; that is, the battery is doing work on the generator and driving it as a motor, but without the polarity of the external circuit being changed. We now have a positive electromotive force, a negative current in the battery, and work done by the battery on the rest of the circuit.

The foregoing is only an illustration of the general law that when the difference of potential between two points on an electrical circuit is of the same sign as the current traversing it, work is being expended on that portion of the circuit; and conversely, if they are of opposite signs, work is being restored by that part of the circuit. It is therefore necessary to know the relative polarities of the current and electromotive force as well as their amounts, in order to have a complete knowledge of the energy of a circuit. The same thing is true of an alternating current, that is, we must know whether the instantaneous values of electromotive force and current have the same sign, as well as the values themselves; and this can only be the case where no self-induction is present, or in the practically equivalent case in which the self-induction is so nearly neutralized as to be of no relative importance.

Referring now to diagram 2, there are shown two curves in the upper figure, E and C. E represents the phase of electromotive force of an alternating generator, and C, the corresponding current through a circuit possessing a certain amount of self-induction. Distances along the horizontal line are taken, as usual, to

represent successive periods of time, and the relative amounts of current or electromotive force are represented by the vertical distance above or below this line, those above being called positive, and those below negative. It will be seen on inspection of the figure, that at the instant (shown at 1) the electromotive force is zero, while at the same time the current has a considerable negative value. Again at the point 2, the current falls to zero, while the electromotive force has risen to the amount shown by the vertical line at 2. At 3, we have an instant at which the current and electromotive force are of opposite sign. Here we have three distinct cases, in the first two of which no work is being done, and

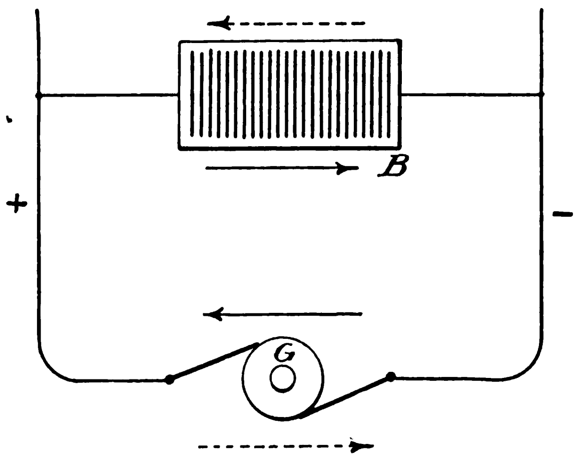

FIG. 1.

in the third, work is being done by the circuit on the generator ; but in each case an effect would be produced on the instruments used for the measurements of electromotive force and current. In fact, taking independent continuous measurements of the electromotive force and current, it is quite evident that the same results would be obtained without regard to the time relation of the phases, so long as the form of each remained unchanged ; and for this reason the result would be the same from such measurements whether the curves were coincident in time, and the current curve occupied the same space as the curve E, or were displaced as shown in the diagram. In the former case, as there is no displacement of phase, the products of the current and electromotive force at each instant would be positive ; that is, work would be done at each instant upon the external circuit except when passing through the values of zero.

The effect of the displacement of the current phase is shown in

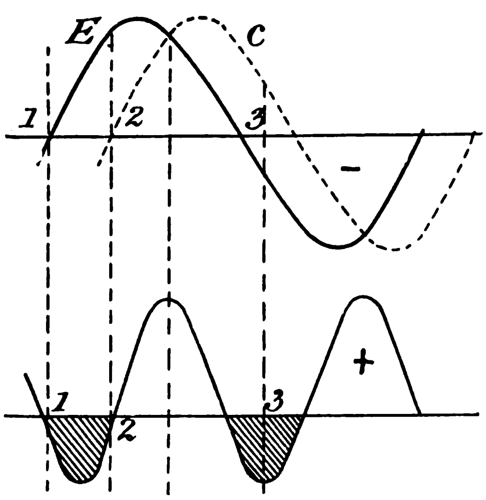

FIG. 2.

the lower figure, where a curve is drawn to show the phase of work done at each instant of time when the lag of the current phase is of the amount here represented. At 1, no work is being done, since the product of E and C contains a zero factor. Between 1 and 2 we have work done by the coil, since the electromotive force is positive at the same time that the current is negative. Then we have a period in which work is expended by the generator : and then at 3 again, work is restored by the circuit to the generator. By still further displacing the current phase the amount of work restored to the generator may be greatly increased. The example I have taken, a retardation of about one-sixth of the phase length, is a very moderate one, and easily realized in practice, and yet the amount of energy restored to the circuit in the work done by the coil is nearly one-fourth of the apparent amount of energy expended, as shown by the product of current electromotive force. The diagrams are not intended to show the exact forms of current phase, or of the phase work done, but they are sufficiently near average conditions for the purpose of illustration.

A retardation of one-fifth of the phase restores about one-third of apparent energy to the circuit, and beyond this point, the proportion restored increases in a high ratio.

The actual work done can never be more than the product of current and electromotive force, and may easily be only a small fraction of that amount.

To show that this retardation is not an imaginary thing, but may have a very decided influence on actual measurements, I will describe two experiments which show phenomena that can be accounted for in no other way, or at least, cannot be explained by the ordinary rules of direct current measurement. An experiment by the writer similar to the second of these was described by Mr. Stanley, in a paper before the American Institute of Electrical Engineers some weeks ago, and is still another example of the same phenomena.

In figure 3, two conductors A and B, are shown, between which an alternating difference of potential of 100 volts is maintained, and indicated on the Cardew voltmeter V. Between these two conductors a third, C, is placed, and two Cardew voltmeters, V 1

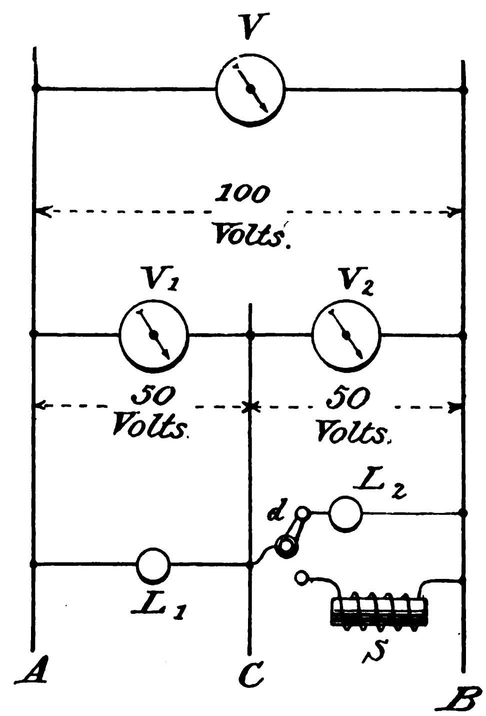

FIG. 3.

and V 2, are connected across the two circuits, and show by the sum of their readings the difference of potential between A and B. They should, under ordinary conditions, agree with the reading of the one at V. Between A and C is connected an incandescent lamp, L, and between C and B, through a switch, *d*, the circuit may be closed either through the lamp L 2, or through a coil of wire S, which surrounds a soft iron core. With the connections as shown in the diagram ; that is, with the switch connected to the lamp, L 2, a perfect balance is obtained, and by adjusting the difference of potential between A and B to 100 volts, we obtain readings of 50 volts on each of the voltmeters, V 1 and V 2. If, however, the switch *d*, be transferred to the point which connects it with the coil S, a somewhat remarkable effect is observed. The readings of the voltmeters at V and V 1, remain constant, since the coil has been so proportioned by trial as to exactly replace the lamp, L 2, and maintain L 1 at exactly the same degree of luminosity ; but the voltmeter, V 2, instead of remaining constant in its indication, as might have been supposed, increases its indication to 80 volts, so that we have our choice, so to speak, of two measures of the difference of potential between the conductors A and B. These are of such large cross-section as to be of sensibly the same difference of potential throughout their length. Measuring at V, we have 100 volts as before, but at V 1 and V 2, we have the sum of 50 and 80, or 130 volts. It is quite evident that there is some condition present, entirely remote from any which could be produced by the action of a direct current ; for it is absurd to suppose that at the same instant of time we can have two separate values

for the difference of potential between the same two points. The natural inference seems that these measurements show in reality only the average of effects which occur successively, although they appear to be simultaneous.

When an impulse from the generator occurs, current flows through V 1, and V 2, instantaneously, and this would give a reading of 50 volts on each if acting alone ; but the same impulse, acting through the coil S, produces a current which, owing to the self-induction of the coil, lags behind the electromotive force, and therefore the coil must restore work to the circuit at some point in the phase. This work is partly expended in the voltmeter connected to the coil, and for this reason it gives a higher reading than the other.

Figure 4 shows a second arrangement in which the current is indicated by a Siemens dynamometer, D, and the difference of potential is maintained constant by the electrometer E. The current may be adjusted to the proper amount by means of the resistance R, introduced in the circuit. An incandescent lamp, L′, is also placed in the circuit in series with the dynamometer, to indicate to the eye any fluctuations in the current. At L, a similar lamp is placed, and around its terminals is shunted a properly proportioned coil, S, surrounding an iron core. A Cardew voltmeter, V, is connected at the same points to show the difference of potential. With the switch closed the normal current passes through the lamp, L, and a difference of potential of 50 volts is shown on the voltmeter, V. The dynamometer shows one and six-tenth amperes to be passing through the circuit, and the electrometer indicates 1,000 volts. On opening the switch a slight increase of current is shown by the dynamometer D, while the difference of potential at E, is constant. The only change in the arrangement of the circuit is that the current instead of passing through the lamp, L, and the

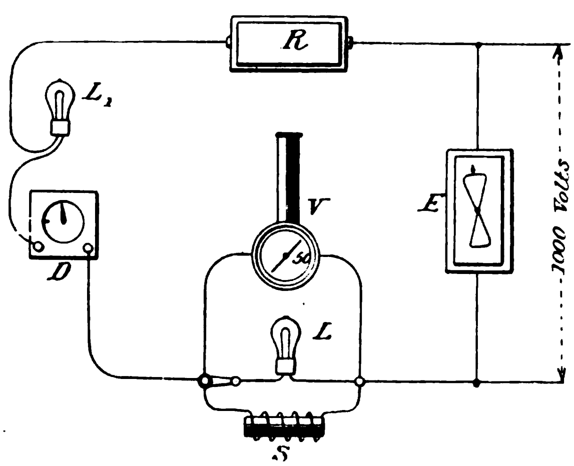

FIG. 4.

coil in parallel, now passes through the coil alone, and yet instead of 50 volts, the voltmeter now indicates 148 volts ; so that we apparently have 98 volts more in the circuit without noticeably changing the difference of the potential at the terminals, and without sensibly changing the current ; or, to look at it in another way, we have, under a constant potential at the extremities of the circuit, introduced an apparent resistance, and at the same time increased the current traversing the circuit. We have here a case similar to the former one, and as the explanation is much the same, it need not be repeated.

The question naturally arises, what influence does this new element of self-induction have upon the possibilities of practical measurements of the alternating current in commercial work? As was stated in the beginning, the practical effect is almost negligible, for there are two cases in which the time element enters to such a limited extent, if at all, that the measurements may be made with perfect success in precisely the same way as if direct currents were employed.

These are, first, the measurement of current through an incandescent lamp supplied by an alternating current directly from the generator ; and second, the current supplied to lamps through the medium of converters with cores far below saturation and carrying a fair proportion of their full normal load. There is a third case, however, which arises in practical work, in which the central station instruments give a somewhat false notion of the actual energy being transferred to the circuits, and this is the one in which a large number of converters are connected to the primary circuit, but with the secondaries open. In this case the effect of self-induction is at its maximum, and there is consequently a lag in the circuit, which in a well-constructed converter approaches the theoretical limit of a quarter phase ; at which point no energy would be consumed, while at the same time a considerable reading might be shown on the current instruments. This apparent difficulty is not a real one, since even the full amount of current shown by the ammeter only constitutes a small percentage of the total output of the plant, and may practically be neglected. Even a small number of lamps in service distributd among the converters greatly reduces this error, and for this reason, even while running with a light load, the ammeter at the central station very nearly corresponds to the number of lights in the service ; while at full load the reading is as accurate as if the current passed directly from the generator to the lamps.

It ought to be evident, however, from what has been shown, that the method which has been sometimes adopted of turning off all the lamps from the secondary circuit, leaving the primary connected to the generator, to show the amount of energy lost in conversion, is apt to give very misleading results unless the proper correction for retardation is applied.

The best proof of economy in the use of converters is, that a test of the power expended in running a dynamo at its normal electromotive force, with its circuit closed through the primary coils of its full complement of converters, is the same as when the primary circuit is entirely open, within the ordinary limits of error of measurement.

THE DISTRIBUTION OF ELECTRICITY BY ALTERNATE CURRENTS.

BY T. CARPENTER SMITH.

THE distribution of electricity by means of alternating currents, though comparatively new in this country, has already reached such an enormous importance that it is with great hesitation that I venture to speak upon it, even though limiting myself to the strictly practical side of the work dealing with the apparatus as we received it from the hands of the manufacturer, and leaving out entirely the question of the efficiency of dynamos and converters. It is only that the knowledge that the mistakes of those who centre upon any new line of business are the rounds of the ladder by which we all attain success, that enables me to lay before you some of the conclusions at which I have arrived after several years experience of varied types of electric lighting, both by the arc, by the direct current incandescent, and the alternate current incandescent.

The subject naturally divides itself into several heads, but I would first say that it appears impossible to lay down any general plan of distribution which would be practicable in all cases. In almost every town a different plan will be required, and this will depend in most cases purely upon local circumstances. Systems that would be admirable for thickly settled and densely populated districts will not be successful in thinly populated and widely scattered ones. I wish it to be understood that whenever I speak in this paper of success and successful systems, I mean successful entirely in a commercial way, and the conditions of this commercial success will vary in every town and district. I will therefore content myself with describing the method which I have found to be most successful in the various districts with which I have had actual experience, and leave it for those who may be called on to design and lay out the lighting of any particular district to judge for themselves which line of action to pursue.

Naturally the first part of my subject is the dynamo, and the station detail. I have tried the small and large dynamo, and have concluded that it is a very great point to properly proportion the right unit of dynamo to the probable size of the station ; that is, not to have dynamos of different sizes, but first to determine what the unit shall be, making it as large as possible, and then make your whole apparatus additions to that unit size. This simplifies matters very much, enabling machines to be interchangeable, both as regards their parts and their work, and this I am sure will be admitted by all who have ever had the annoyance of a break-down on engine or machinery when perhaps they had standing idle plenty of apparatus, which, from various circumstances, could neither be used itself, nor be robbed to repair the break-down.

I would drive each dynamo by a separate engine, and this for several reasons : by proportioning the engine to the dynamo, it will be possible to have the engine running slightly overloaded when the dynamo is doing its utmost during the hours of heavy lighting, and as this extreme load falls off to the lighter hours of running, the engine will be working at its point of best economy, instead of running underloaded, and thereby wasting steam. Thus we use in our station on Virgin alley dynamos of 2,500 light capacity each, driven by 200 h. p. engines. During 16 hours of the day these dynamos run driving 2,000 lights, and the engines are cutting off at quarter stroke and developing 200 h. p. During the other 8 hours we have driven these dynamos as high as 2,800 lights, during which time the engine was of course overloaded, and not working to so good an economy, but eight hours of overload is not nearly so wasteful as 16 hours of underload ; again we have had it very forcibly demonstrated more than once that if the engine be only large enough to drive the dynamo with ease, a heavy short circuit on the mains outside will simply pull the engine up or slow it down, without destroying the dynamo, and only those who have seen a 9-foot fly-wheel running 250 revolutions per minute on a 200 h. p.

engine, slowed down in almost an instant of time, can realize the terrific strain to which everything is subjected in such cases, and I would mention right here that the element of time is a very great factor in such circumstances, as in an accident of this kind mischief is often done before the safety catches can melt out. The direct belting of the engine to the dynamo is always to be preferred; shafting is, except under exceptional circumstances, simply a nuisance for incandescent electric light stations, and the economy of one large engine over many small ones has been enormously overrated. For arc light work, where the lights are all lit and extinguished at certain hours, the large engine is good, but for incandescent work, where the load is absolutely out of the control of the station, it is impossible to steadily run a large engine at anything like its most economical load, whereas, with separate engines the machines can be started and stopped the moment that they are needed or are done with, while the oil from shafting will always cause more or less grease and dirt.

For central station use, except for very small plants, I should certainly use separately excited dynamos, and should do the exciting from two or more dynamos each capable of exciting the whole system. In this way, with the station running at its normal, the only regulation required is that obtained by working the simple rheostat in the field of the motor, and as we have designed our station at Pittsburgh, this will mean the regulation of 15,000 lights by one 6 inch hand-wheel.

Of course each dynamo should have its separate field rheostat to make up for any slight difference in speed of engines. The two exciters should be so arranged that they can be run together or separate, or that either can do the whole work, which, of course, is easily accomplished by feeding them into a separate pair of exciter bars on the switch-board, and charging the fields of alternating dynamos from these. The general question as to whether it is better to use separate circuits for separate machines, or to couple them into a general set of 'bus wires, and distribute from them, is too large to be lightly decided, as also is the question as to whether it is best to run separate circuits for separate districts or to run into a general system of high pressure mains outside of the station, feeding into these mains at different points, and again distributing from them, and I am not prepared to express any preference, but think that local circumstances will generally decide this question. There seems to me little doubt that in underground systems the net work of high pressure mains would be the best, but for overhead work we have adopted the system of separate circuits from separate dynamos, using a switch-board which enables us practically to run any circuit or any number of circuits from any dynamos, and running these dynamos separately and not in multiple arc. In spite of the utmost precautions, the unregenerate telephone and telegraph men are always hauling wires across our high pressure mains and feeders, and while their wires and not ours generally suffer, after hearing the frightful roar that comes from the dynamo which is running the particular circuit so crossed, we always feel relieved to know that only one dynamo is in danger of being thrown out by the slipping off of the belt, and a 20-inch belt is not a pleasant thing to have flying around loose. In case of any trouble, such as fire, circuit broken down, or anything of that sort, we can pull the switch of that particular circuit, until we can cut out the part affected. The system that I have laid out for use here will, of course, take a long time to introduce, in view of the fact that we are changing from one system to the other, and have to be governed largely by the location of our lighting, our existing lines, and the possibility of putting up additional pole lines, but it takes in my vision the form of a series of heavy mains down the main streets with cross lines on the cross streets, with switches on the poles enabling any of the cross streets to be run from the mains on either of the main streets, so that in case of a fire on one of the main streets the section represented by the block in which the fire occurs, can, by the pulling of two switches be completely cut off, while the cross streets on either side of the section will enable the lights beyond the fire or broken circuit to be operated, with only the trouble of a slightly larger percentage of loss and the consequent dimming of the lights.

For the main overhead wires, I must harp upon the old string which cannot be struck too often, namely, high insulation. For 100 volt current work, the old standby of "undertakers'" wire will pass; but when it comes to 1000 volts difference of potential, and 130 or 140 amperes to back it up, one realizes very quickly that nothing is too good to curb this fiery steed. We are still paying the penalty of early ignorance in having many circuits of underwriters' wire stretched upon our poles, and I have stood and listened with fear and trembling to the howls of a new dynamo which had only been in operation for a few hours, when we had four short circuits in as many minutes, caused by dead wires falling across these mains on a wet day; while on the other hand I have been gratified beyond expression to see our linemen remove 10 or 12 old bare iron "District-call" wires which had been hanging all night right across our high pressure high insulation mains, and this during a soaking rain. Especially should the service wires to the converters be of the best insulation, not only for fire, but for protection to life, for while the shock does not kill, even a 100 volt shock may make a man start so as to fall off a ladder; and any death or injury will be credited to the electric current. We have adopted a standard of a separation of three feet between the two wires nearest each other on the cross-arms, and do not allow, under any circumstances, the tapping of service lines directly to these wires. All services must be attached through the medium of a small spreader on the end of the cross-arm, which I have no doubt all those present have noticed on the streets.

In some districts where the number of lights in each building is small, we run secondary low pressure mains, and place the converters on the poles, and make our distribution from our secondary mains, but our experience has been that this is not a very satisfactory way of doing. The percentage of loss on those secondary mains, unless the wires are very large or the converters very numerous, either of which is objectionable, causes such a decided variation in the lights as to give ground for numerous complaints.

The question of the loss on the high pressure feeders and mains is one which I think has not received enough attention. When the alternating system was first introduced, so much was said about the extreme smallness of the wire required that a great many of the arc light fiends throughout the country who had been accustomed to congratulate themselves on the fact that No. 6 wires was big enough for a 20-mile circuit, immediately jumped to the conclusion that because it was a high tension current, No. 6 wires was big enough for all cases, and consequently more than one case of dreadful grief has arisen. I have laid out our circuits on a certain fixed plan, which is, that each circuit shall be laid out for 1,300 lights (that being the size of unit which we at first adopted) and made of such sizes as to carry these 1,300 lights with a loss of not more than two per cent. with the whole load on. By having feeders large enough for this, we prevent any noticeable differences in candle power from one end of the circuit to the other, and should we be even compelled to run a light circuit and a loaded one on the same machine, the increase in the one or the decrease in the other would not be injurious. Of course, we try to so arrange our circuits that the load shall vary about the same on each, but the suddenness with which storms creep up in Pittsburgh makes our load very uncertain and erratic. We have run for three days and nights with only a little more than half of the machinery in operation, and then from Monday night to Friday morning have had to run every incandescent machine in the station under a load that fairly staggered it.

I now come to the question of the placing of the converters, and for this I think that you may safely lay down the general rule that wherever you are simply carrying current, do it at high pressure, and keep your low pressure for the purely local distribution. With proper precaution, I do not see that there is any real danger in carrying the high pressure wires into and through the building. If a 1,000 volt current from a central station is not to be allowed in a building on account of its dangers, then every arc light plant, whether from central station or an isolated plant in the building, must be condemned for the same reason. Of course, the cases where two wires of an arc circuit with a difference of a potential of 1,000 volts are run close together, are not nearly so many as must be the case where there is constant difference of potential of 1,000 volts in the alternating system, and again, of course, we have the fact that the direct current on arc circuits is generally not more than 20 amperes, while, as I have remarked before, our alternating circuits run as high as 130 amperes; but the fact that one is a direct, and the other an alternating current largely makes up for this difference. With all due respect for the many gentlemen who have discussed so learnedly of the deadly alternating current, and on the frightful results therefrom, and whose experience with the alternating system is mostly confined to the magneto bell or induction coil, I must maintain that the alternating current, while it is in mild doses of from 100 to 200 or 300 volts intensely more disagreeable than the direct current of the same voltage; when it comes to 1,000 volts or more it is very much less dangerous to life. I make this statement with the more confidence that I have tried them both, and we have in our station here not one but half-a-dozen cases where our linemen and dynamo men have received the full 1,000 volts, generally being pretty badly burned at the point of contact, but experiencing no ill after-effects, while whenever any of our men receive a shock from one of our arc machines they are nearly always sick for a day after. This very fact of the alternating current being more disagreeable adds to its safety, as the men are disinclined to work on the wires, even when there is only a slight leak, where with the direct current they will often take much greater risks. In carrying our high pressure wires through the buildings, we have adopted the invariable rule that they must be carried on porcelain insulators, and the wires themselves waterproof in all cases. We do not allow them to be run in moulding, but where the wires are to be concealed or protected a casing is run around the wires, outside of the porcelain insulators, and hard rubber must always be used for floors and walls. The converters are all placed with porcelain knobs behind them, giving an air space of two inches between them and the wall, and we prefer in all cases to put them against brick, rather than

against wood or plaster. I understand that in some districts the use of converters inside buildings has been forbidden, but I think that this position is a most unjust and untenable one. The only argument that can be brought against their being placed inside is the danger to life or of fire. For the first the converter is well insulated, and is placed high up out of reach, and most potent argument, though one, I am sorry to say, often refused recognition, is, it is not placed there to be handled. As regards the danger from fire, all the converters with which I have had any experience are boxed up completely in iron cases, the only opening in which is a small one at the bottom for ventilation. They cannot possibly get hotter than the melting point of lead for the simple reason that if they should the fuses would blow out and cut them out of the circuit, and any one who has performed the old experiment of melting lead in a piece of paper can easily see that this heat is not liable to set anything on fire, and even should the converter burn out no flame can escape from it to set fire to anything, however inflammable. If the converter is to be banished from buildings on account of danger from fire, then every stove, high pressure steam pipe, and for that matter every gas jet must also be banished.

In a Chinese fire cracker lately published, I find the statement that inspector McDevitt has relegated to the celler all converters, and that he says that in the first case of explosion or fire from them, they will have to go to the street. Now, as vice-president of the company owning these converters, I have simply to say that this is not so, and that the converters are placed all through the buildings, wherever we may desire to have them, and only three or four are in cellars. Moreover, so far from Mr. McDevitt making any such statement, he has steadily refused, even under the most urgent solicitation of the Chinese gentlemen, to make any such restriction, but has very properly stated that until an explosion or fire occurred, he can take no such action. I speak of the publication as a "fire cracker" for three reasons,—first, because it is red; second, it is chiefly noise; thirdly, a good many crackers are only fizzles.

As regards the liability to burn out, and the dangers therefrom, I can only say that from over 600 converters of all sizes from 5 to 50 lights each, in an experience extending over 12 months of constant service night and day without any stop, we have had but three actual cases of burning out, two of these being 5-light converters, and one being a 50-light converter. The two 5-light converters were simply slowly roasted out from overloading, until finally the insulation on the primaries was charred through, when the fuses blew out instantly, and all was over. In one case the customer had been attracted by the converter singing, and was standing looking at it when his lights suddenly went out, and he had to go into a neighbor's store to know whether the trouble was in his lights only, or with the main circuit. The 50-light converter suffered in the same way, having nobly endeavored for some two days to run 120 lights. It was one of three on a section of secondary mains, and the lineman who had been sent out to examine them owing to complaint to us of poor light, reported that two of them were all right, as they were cold, but that one of them was bad, as it was very hot, and preparations were being made to change this converter, when a message was received from one of our customers that the "stove on the pole" in front of his place was smoking.

Investigation showed that both plugs in the other two converters were blown, and the only reason that this one had not followed suit was the fact that some ingenious gentleman had made them of copper. We have had three cases of defective converters; that is, converters with a wire broken inside, or short circuited, so that the moment that the current was put into them, they would blow out all the fuses, and if new fuses were put in, they would again immediately blow, but the men in these cases of course immediately returned them to the shop for examination; that is to say, out of the 600 converters, we have actually had to remove or repair one per cent. in actual service, and I submit that on a total converter capacity of 17,000 lights, this is a very good proof that these converters are well made and not dangerous.

In all of our experience, we have not had one single case of connection between the primary and secondary, or the primary and the shell of the converter, even in the case of the burned out converters, and we had just a few days ago the first case of a connection between the secondary and the shell of the converter, and this last was found upon examination.

We started with the idea that it was better in cases where we had from the number of the lights in a building to use more than one converter, to bank them; that is to say, connect all the primaries and all the secondaries in multiple, and distribute from this 'bus wire, but two or three peculiar experiences have led us to change our plans, and never to do so if it can be easily avoided. We had two or three unfortunate cases where one converter of a bank for some unknown reason would blow its plug, thus overloading the others, then, perhaps, another would give way, and thereafter it was a race as to which would blow its plug the quickest. It is not calculated to make one feel comfortable to have 400 lights in a theater go out at once, just as the curtain was about four feet from the stage, in the beginning of the third act, yet this was our experience last Christmas day. We had the converters fused up and running in half an hour, but next day the same thing occurred, though the gas man seeing the lights dim down was quick enough in shutting off his different circuits to stop three or four converters, which gave him lights enough to pull through. We have cut this building up, and each converter now carries its own load with the result of our detecting one of them which for some reason unknown always tried to do more than its share of the work, but while we have marked it, we have not troubled to change it, as, working singly, it does its work well. We have had another case of the same kind in another bank of converters, which have also since been cut apart, and we found the trouble arose from a poor connection which heated up the fuse to melting point; yet, as we have in the City Hall two banks of 13, 10-light converters each, and in the Union Station a bank of 25 10-light converters and 8 20-light converters, which have never had the current off them for nearly three months, and have never had a single converter of all these blow its fuses, we cannot say that this result would always or even generally obtain; but as the object of banking is primarily to prevent the total extinction in case of one converter going out, and as this is better attained by the judicious running of the secondary circuits, we prefer keeping the converters separated.

For the secondary wiring in the buildings we need lay down no laws. The rules governing this are too well known to need any repetition. One advantage of the alternating system, which was first brought to my attention by one of our wiremen, is the fact that wires carrying the alternating system do not blacken the surface on which they run. We have in our station circuits of direct and alternating currents side by side, put up at the same time, on a ceiling painted in very light colors, and which have been burning the same number of hours. The paint under the direct current wires is very dirty, in the usual style, and the wires themselves are covered with black deposit, while the alternating current wires, and the ceiling on which they lie are as clean as when put up.

There yet remains one point on which I wish to say a few words, and it is a subject of the greatest importance. Now that the alternating current distribution is a pronounced success, there is no reason why the places of all others where incandescent light is most desirable, namely in residences, should not enjoy the advantages and improvements from which they have been hitherto debarred by their distance from the usual centre of distribution, and it is when we bring electricity into the dwelling house, where it will be daily and hourly needed and handled by women and children, that we realize how absolutely necessary it is that we use anything and everything that can tend to make safe its introduction and manipulation. Of course, the first and second of these are, good insulation, better insulation, and best insulation; but besides this, there are other points to be considered, and one that seems to be worthy of very careful consideration, and the fullest discussion, is that which has been more than once suggested, namely, the making of permanent ground connections with the secondary wires. The object of this is, of course, that should a leak occur at any point between the primary and secondary, the current being already grounded, will render it impossible for any one to receive a shock by touching the secondary and at the same time making an earth connection. When I first considered this question, I said in my haste that such was not a proper course of action, as one is simply provoking a ground at some other point, and seeing the careful insulation of the converters we use, I could not see any danger of a leak across, and I have considered and heard some discussion both pro and con, and for this purpose I should like to hear the most bitter partisans on either side, that we may get from them every little weakness on either side of the question brought out.

In a paper like this, it is impossible to do more than to give the merest sketch of the subject, but I trust that what I have said may be the means of inviting discussion and inquiry, for it is only by this means that we can arrive at the true facts of any case, and, as we all know, the electric light industry has suffered more than tongue can tell from the general ignorance of its dangers and requirements, which hindered and injured its early introduction into this country, and which led to the spending of so much good money on plants and wires which were not merely insufficient, but absolutely dangerous.

Now that we have taken, as it were, a new departure and entered into a new era of progress, let us not fall into the same errors which marred the early history of our business, but strive with might and main, by discussion and interchange of experience, to make each new installation another stride towards perfection in what I think is undoubtedly the greatest achievement of the age—the distribution of electricity by alternate currents.

ELECTRIC MOTORS.

BY DR. G. A. LIEBIG, JR.

THE development of the electric motor from its primitive form up to the present state of advancement and usefulness has been similar to the growth of nearly all of those great discoveries, which have proved themselves at first so adaptable and then so necessary to the wants of every day life.

The history of the motor is a very remarkable one, not only as a story of rapid improvement but also because its first chapters belong to recent times.

We can now ask ourselves, not without some astonishment, why it happened, seeing that the laws of the conservation of energy were so generally accepted, that the reversibility of the dynamo and motor was so lately discovered. It is quite true that the first motor was built many years ago, but for a long time even after the dynamo had undergone a very marked improvement, the motor was not turned to practical account. In other words, dynamos and motors have all along been kept distinctly apart, and even to-day there exists sometimes a certain indefiniteness about their relation.

We know that the general term "dynamo-electric machine" includes not only generators of electricity, but also appliances for converting electricity into other forms of energy, and that all the mathematical formulas which have been applied to the dynamo as a generator of electricity are equally as applicable to the dynamo when viewed as a source of motive power. The only changes necessary in our formulas relate to the algebraic signs of certain symbols.

The feature of reversibility is of extreme importance, and means that any rule of construction or of design that tends to make a dynamo machine an efficient apparatus will give identical results when used in connection with a motor. Other considerations may present themselves, questions of speed and output per unit weight of material may arise, and these may be different in the two cases, but they are of a mechanical or at any rate secondary interest, and in no way affect the mathematical considerations. In what follows, therefore, we shall use the term "dynamo-electric machine" to designate, unless otherwise specified, either a generator of electricity or a dynamo reversed, *i. e.*, a motor.

In order to give an intelligible review of the work done on dynamos, and prepare the way for a few considerations which will follow, it may be well to describe briefly the component parts of a dynamo-electric machine, and refer to the purposes for which they are intended. In every dynamo we must have a combination of the following elements:—

(*a*) An iron body or frame work constituting the magnetic limbs. This is always wrapped over a certain portion of its length with insulated copper wire and its purpose is to produce between its ends or polar surfaces a region of magnetic force.

(*b*) A series of coils of copper wire generally wound upon a subdivided mass of iron, and capable of revolution about an axis in such a way as to make each coil pass successively before the polar surfaces of the magnetic limbs. This is called the armature, and is always so placed that it helps, with the magnets, to form a nearly closed magnetic circuit of iron.

(*c*) A commutator, which is merely the ends of the armature coils brought to one side, and which revolving with the armature effects a change in the direction of the currents formed alternately plus and minus.

(*d*) Several brushes or collectors, usually two in number, consisting of pieces of metal which press upon the segments of the commutator, and which are in metallic communication with the terminals of the machine.

In general, the armature revolves between the poles of the electro-magnet; but in some machines, notably those intended to furnish alternate currents, the armature is stationary, and the magnet coils themselves revolve. This is however immaterial, inasmuch as what we have to consider is the relative motion of the parts of the machine, not their absolute movements.

It appears, therefore, that the dynamo machine since it consists, broadly speaking, of an electro-magnet and a revolving coil of wire is a very simple piece of machinery, yet it has taken years of hard labor and patient investigation to evolve from the spinning disc of Faraday the dynamo of to-day.

There is a feature in the history of the dynamo which must appear remarkable to every one thinking of the subject. When we remember how much attention has been directed to dynamo machines, not only by practical but by scientific men, and recollect that all the materials for a complete theory of the dynamo have been for several years at hand, we are inclined to wonder at the absence of such a theory. Even to-day no complete theory exists, though we are in an immeasurably better position in this respect than we were five years ago. For what we know now in so far as it is immediately applicable to dynamos, we are mainly indebted to the labors of Clausius, Hopkinson, and a few others. It is sometimes claimed that the theory of the dynamo has been seriously crippled by the want of sufficient knowledge regarding the law of the electro-magnet, namely, the law connecting magnetic force with the magnetism thereby produced in magnetic bodies. If we admit that an empirical formula is required we must admit the justice of the claim, because no accurate expression of this kind has ever been originated. But we shall see that it is by no means necessary to depend upon empirical laws; all that we require are the curves of magnetism, and these have been before the world for years.

However, we now possess the results of a new series of investigations as to magnetism and a magnetic permeability undertaken at home and abroad, among which the most important are those of Hopkinson, Ewing, Rowland, Warburg, etc. These results, in connection with the work already referred to, make it possible to calculate to a close approximation, at least for certain forms of machines, just what any given dynamo will do when we know besides its dimensions and configuration the kind of iron used in its manufacture.

The words magnetic permeability used above, and which enter so frequently into dynamo calculations are defined by Maxwell (vol. ii, page 50) as the ratio of magnetic induction to magnetic force. It is also called magnetic inductive capacity corresponding to specific inductive capacity in electro-statics.

Following out an analogy in a different direction, it sometimes happens that magnetic permeability is called magnetic conductivity or resistance, the idea being to express the varying resistance offered by a given body to the production within it, of "lines of induction," as the lines of flow are opposed by a porous solid through which is forced an incompressible liquid. Further we know (Maxwell, vol. ii, p. 51), that the magnetic induction is related to the magnetic force in exactly the same way that current is related to electromotive force; namely, we have,

$$B = \mu H \text{ and } C = K E$$

where μ is the permeability and K the conductivity. But the analogy is in a sense imperfect, for whereas K is a constant, in so far at least as it is absolutely independent of the current flowing (leaving all heating effects out of consideration), μ is by no means a constant, but depends not only on the present state of the material in reference to the induction within it, but also upon its previous magnetic history. Thus μ is a variable quantity, and for magnetic bodies grows less and less as the magnetizing force increases. We can, therefore, regard the analogy between B and H on the one hand, and C and E on the other, as holding good only when H is a very small quantity.

In the calculations applied to dynamos, it is extremely important to know the distribution of magnetism over the polar surfaces of the electro-magnets, that is the number and direction of the lines of induction from pole to pole.

A solution of this problem can be arrived at mathematically in an approximate way only, and then, as a rule, by the consideration of what takes place in the least complex forms of surfaces.

To attain certain ends the graphic method may be applied, either roughly by the use of iron filings, or more carefully by the employment of a small magnet suspended by a silk fibre. By observing the positions assumed by the magnet when freely suspended in different regions of the magnetic field, we can form some idea of the form of the field. For we know that the direction given by the magnet coincides with the resultant direction of the magnetic force at that point (the needle being supposed so small as to exert no disturbing influence) and also that the relative number of lines of force in a small space surrounding the point measures the relative field intensity. The positive direction of the lines of force may be taken as from the north pole to the south pole, both outside and inside the magnet, and they are related to lines of induction in this way: outside the magnet they coincide; inside the magnet they are in opposite directions. This amounts to saying that the lines of induction are continuous, whereas the lines of force are not.

Other methods of measuring the field intensity of dynamos have been proposed, such as the magnetometer method. The results so obtained are however inaccurate, and indeed the method cannot be applied at all when the armature is in place. Nor can the very simple pendulum method devised by Sir William Thomson be applied, because the air space between armature and magnets is too small. It can of course be used by removing the armature, and it has the advantage of giving results directly in absolute measure.

Unfortunately, measurements obtained under these circumstances do not give us a reliable basis for calculations, inasmuch as the form of the magnetic field is strongly influenced by the presence or absence of the armature, at least when it contains iron. It may be remarked that magnetic distribution is exactly analogous to electric distribution, especially in the case of dielectrics, and that the geometrical form which influences the latter plays almost as important a part in the case of magnetic distribution.

We are aware that the density of electricity on a given portion of a charged body depends upon the shape of the body and also upon the presence near it of other charged bodies. The same laws of surface density determining the so-called leakage of lines of force obtain in the case of magnetism. In almost all dynamos the pole-pieces have necessarily somewhat sharp edges, and the number of lines of force obtained per unit area is probably greater at the edges than over the remaining polar surfaces. This number is subject to a change when the armature is in place, and to a further modification when the armature revolves, on account of the change in the direction of the axis of magnetization of the latter. These considerations show us that any system of measurement which will give useful results must be of such nature as to be applicable to the dynamo when in working order. The ballistic

method fulfills these requirements; it is sufficiently accurate, and besides involves no special difficulty. We have simply to surround that part of the magnetic circuit of which we want the induction with one or more turns of copper wire connected with a ballistic galvanometer and observe the throw of the galvanometer needle when the magnetism is reversed or reduced to zero.

It is always better to observe the elongation of the galvanometer needle due to a reversal of magnetism. An uncertainty always attends a reduction to zero owing to the phenomenon of residual magnetism. The galvanometer having once been calibrated in absolute measure, we can from the throw of the needle calculate the value of the total induction within the wire, and the magnetic force is known from the data of magnetizing current and number of convolutions. The experiment is repeated for the different parts of the machine, so that we finally obtain the value of the induction throughout the entire magnetic circuit. Suppose now that we have measured the field intensity and have a value of the induction per unit area; we can, by Faraday's law, calculate the E.M.F. which would be set up in a conductor moving in any manner in the field. The law is this: The E. M. F. produced in a conductor moving in a magnetic field is equal to the rate of cutting the lines of force. If the conductor forms a closed circuit, the E. M. F. depends upon the area of the circuit. Hence, in order to be able to determine the E. M. F. produced in an armature, say, we must know the area of the coils of the armature, the strength of the magnetic field, and the velocity of rotation. Call the total number of lines of induction (flow of force) passing through the armature N and the current γ then, we have for the force x acting when the circuit is displaced through the distance $d\,x$, by the principle of the conservation of energy (Maxwell, vol. ii., p. 137):

$$X = + \gamma \frac{d\,N}{d\,x}.$$

Hence, the movement is aided or resisted according as the number of lines of induction passing through the armature is increased or diminished by the movement. The work done during the displacement, is

$$X\,d\,x = \gamma\,d\,N,$$

and if the number of lines of induction is changed from N to N, we have for the whole work:

$$\int X\,d\,x = \gamma\,(N' - N).$$

Let us divide both sides of the equation by $d\,t$, and we have:

$$X \frac{d\,x}{d\,t} = \gamma \frac{d\,N}{d\,t}$$

as the rate at which work is done. But $\frac{d\,N}{d\,t}$ is the rate at which the lines of force are cut by the moving conductor and is equal to the amount produced in that conductor. We have, therefore, for the rate of doing work—the activity:

$$\gamma\,e = \frac{E - e}{R}\,e,$$

the well-known expression for the activity of the motor.

We shall now simply refer to the investigations of Clausius,[1] and Hopkinson,[2] as their work though differing in character is of extreme importance. The theories published by these two scientists are distinct and characteristic of the two ways of regarding magnetic phenomena. Hopkinson's method is based upon two fundamental laws of electro-magnetism; one law expressing the relation between currents and magnetic force, the other a condition which always holds for magnetic induction. They are as follows: The line integral of magnetic force around any closed curve is equal to zero, unless the curve surrounds a current, in which case it becomes four π times the total current through the curve; the other is the equation of continuity applied to magnetic induction, which means that a line or tube of induction cannot end at a point in space. According to the last law, therefore, if we find that the magnetic induction has different values in the different parts of the magnetic circuit composing the dynamo, we know that there has occurred a leakage through the air. For instance, the total induction through the armature in every dynamo is less than the total induction through the magnet limbs; the excess has, therefore, passed beyond the limits of the iron body into the air from pole to pole.

The two laws just given furnish a means of constructing the characteristic curve with considerable accuracy, *a prior*; that is, the curve showing the relation between electromotive force and current, for the total induction nearly proportional to the induction through the armature at a given speed determines the E. M. F. generated. The data required for calculating the line integral of magnetic force are: first, the general configuration of the dynamo; specification of the kind of iron used; the sectional areas; the lengths of the different parts of the machine; the magnet limbs; armature yoke pole-pieces; and from these the "magnetic lengths" can in general be estimated. The variables chosen are the total induction through the armature and the current around the magnets. Certain co-efficients occur in the equations expressing the relation between the induction in the armature and that in other parts of the dynamo; they are approximately constant, and can be estimated when their values for a machine of given form are once known. Hopkinson's equation can be thrown in the form,

$$\Sigma\,l\,f\left(\frac{v\,I}{A}\right) \quad 4\,\pi\,n\,c,$$

Σ denoting summation. I is the induction through the armature and the function f depends upon the qualities of the iron in the machine. In a machine in which experiments were conducted by Drs. J. and E Hopkinson, the difference between the induction through the armature and magnets amounted to about thirty per cent. As an indication of the power of the method and the accuracy with which results obtained from one machine can be applied to dynamos of every different form, it may be recalled that the characteristic curve of the "Manchester dynamo" was constructed before the machine was built, and was found to require no correction afterwards. In this case the dynamo possessed not only an entirely new form, but was also compound wound.

The theory of Clausius is founded upon considerations of a totally different character, and is undoubtedly less readily adaptable to practical manipulation. The theory is based upon Ampere's well-known laws of the action of currents upon conductors; an action which is supposed to take place at a distance and not through an intervening medium, as explained by Faraday, Maxwell, Thomson, and others. Clausius expresses in his fundamental equations the mutual potential of the currents of the dynamo upon one another, and to determine the magnetic moments of the magnets and armature he adopts, with, however, considerable unwillingness, Frœlich's formula of induced magnetism. This formula has been extensively used, and generally under the form:

$$M = \frac{a\,i}{1 + b\,i}$$

in which a and b are constants and i the current. There has always existed a more or less marked opposition to Frœlich's formula, as not giving results in accordance with experiment though the curve it represents is a practically straight line near the origin. Investigation has shown, and Hopkinson has called attention to the fact that the curve should have a point of inflection at the origin, and hence it must be slightly concaved downward (that is, toward the axis of abscissae) during the first part of its course.

Clausius has remarked that it would be better for a dynamo if the core of the armature remained stationary while the coils alone revolved. Mechanical difficulties, of course, preclude the possibility of such an arrangement; yet, we shall see that other considerations support the views of Clausius. In the case of two machines, one used as dynamo and one as a motor, the author has shown that the velocities of rotation necessary to secure maximum work are not in the ratio of one to two as generally believed, but approach this value as the speed of the generator is increased. This, however, refers to the condition existing when the work done by the generator, is not limited. When the work is determined, he shows that there can be no relation between the speeds of the machines in order to give a maximum of work done by the motor.

Another theory, though scarcely a distinctive theory, has been advanced by Dr. Frœlich, and much work of a theoretical character, besides that mentioned in reference to dynamo-electric machines, has been done; but the most important have been referred to.

There is one point which may as well be mentioned at this place about dynamo construction, which seems to have been the origin of exceedingly contradictory opinions.

It is in reference to the position which the coils of wire should occupy on the field magnets. In some cases, we find the coils heaped up toward the middle of the magnets; in some cases, toward the pole-pieces, while in by far the majority of machines the coils are evenly distributed along the whole length.

Theoretically the latter system of winding should be just as effective as the others, and being less complicated, should be used on that account. Professor S. P. Thomson recommends in his work that the layers should be most numerous around the middle of the magnet limbs; in support of which view, he calls attention to the form and number of lines of force from a straight bar magnet in which there is a leakage all along the bar from pole to pole.

The conclusion, however, is unwarranted and the comparison valueless, because in dynamo machines we are dealing with as nearly as may be closed magnetic circuits, and because the dis-

1. J. Hopkinson, Proc. Roy. Soc., 1888.
2. Clausius, Phil. Mag., 1888.

tribution of magnetism under such circumstances is entirely different from the distribution in bar magnets, whether long or short. The remedy for leakages which do occur is to be found not in the peculiar shape of magnet coils, but in the qualities of iron and lengths and sectional areas of the magnetic circuit.

The question of the regulation of motors now demands our attention, and we shall have to consider the methods adopted to meet the requirements of the two systems of electric distribution now in vogue. We can say two systems, because up to the present, motors have not been successfully used on alternating current circuits whatever may happen in the near future. The two systems known as the constant current or arc light and constant potential or incandescent lamp system, necessitate methods of regulation in motors, which are entirely different. For constant potential work we can use either a shunt motor or a "compound wound" machine. In the latter, the main or shunt coils are in shunt with the armature and series coils, or with the armature alone, the series coils being wound in a direction opposite to that of the main magnetizing coils. This system seems to have been first proposed by Messrs. Ayrton and Perry, and is described at some length in Thomson's book on Dynamo-Electric Machinery. Bosanquet (Phil. Mag. vol. xv., p. 275) arrived at a law of winding similar to Ayrton and Perry's, but deduced from entirely different considerations. The elementary theory of machines of this type is too well-known to require special attention. It is sufficient to say that machines so constructed regulate very perfectly (that is, run at a practically constant speed), and have been extensively used. It is however by no means necessary to employ a differential winding of field magnets as has been mentioned in order to secure regulation. The same results are attained by the use of a simple shunt arrangement, provided there exists a certain relation between the resistances of the shunt coils and armature. Indeed, many constant potential dynamos with excellent regulation have already been made in this manner, and motors on the same principle are rapidly coming forward.

It has been stated that compound wound motors (that is, shunt motors, with series regulating coils) will not run at an invariable speed when the load changes if supplied with a constant current, unless the speed is such as to reduce the efficiency to 50 per cent. or less. The statement seems inaccurate; an efficiency of 50 per cent. having nothing to do with the regulation, as we shall see by examination.

Let us consider the matter for a so-called "long shunt" motor. Call now:

E, Electromotive force of supply.
e, Counter E. M. F. developed.
R, Resistance of armature.
r_s, Resistance of shunt coil.
r_m, Resistance of series coil.

Then we have for the rate at which energy is supplied to the motor:

$$\frac{E(E-e)}{R+r_m}$$

and for the rate at which work is done by the motor:

$$\frac{e(E-e)}{R+r_m}=W.$$

Regarding now both with W and E, as functions of the counte E. M. F., we have by differentiation:

$$\frac{dW}{de}=\frac{E-e}{R+r_m}+\frac{e}{R+r_m}\left(\frac{dE}{de}-1\right)$$
$$=\frac{E-2e}{R+r_m}+\frac{e}{R+r_m}\cdot\frac{dE}{de}$$

If the potential of supply is constant, then $\frac{dE}{de}=0$, and the equation reduces to its first term. In this case, we see at once that the differential coefficient of W, with respect to e is positive or negative, according as $E > 2e$ or $E < 2e$. This means that as the load increases we can keep that speed constant by diminishing or strengthening the field, provided the efficiency is greater or less than 50 per cent., and this is well known. Suppose now that E is variable but that the current is constant; then we have:

$$K=\frac{E}{r_s}+\frac{E-e}{R+r_m}.$$

Differentiating, we have:

$$\frac{1}{r_s}\cdot\frac{dE}{de}+\frac{1}{R+r_m}\left(\frac{dE}{de}-1\right)=0;\text{ or}$$

$$\frac{dE}{de}=\left(\frac{1}{r_s}+\frac{1}{R+r_m}\right)=\frac{1}{R+r_m};$$

or putting $\rho=R+r_m$, we obtain:

$$\frac{dE}{de}=\frac{1}{\rho}\cdot\frac{r_s\,\rho}{r_s+\rho}=\frac{r_s}{r_s+\rho}.$$

Substituting in our first equation this value of $\frac{dE}{de}$, we get:

$$\frac{dW}{de}=\frac{E-2e}{\rho}+\frac{e}{\rho}\cdot\frac{r_s}{r_s+\rho}$$
$$=\frac{E(r_s+\rho)-e\,(2r_s+\rho-r_s)}{\rho\,(\rho+r_s)}=\frac{E}{\rho}-\frac{e}{\rho}\left(\frac{2\rho+r_s}{\rho+r_s}\right)$$

and, therefore, $\frac{dW}{de}$ is positive or negative; that is, the rate at which work is done increases or diminishes as e increases, according as:

$$E > \text{ or } < e\,\frac{2\rho+r_s}{\rho+r_s}$$

or, according as the efficiency:

$$\frac{e}{E} > \text{ or } < \frac{\rho+r_s}{2\rho+r_s}.$$

This quantity, in the kind of motor under consideration is nearly unity, because the shunt coils have a resistance very great compared with that of the series coils or armature or both together.

The question of an efficiency of 50 per cent. does not therefore enter.

A better way to arrive at some knowledge of the regulation is to introduce an expression for the torque into our equations.

If we denote the speed by n, and call T the torque or work per turn, we have for the rate at which work is done in the motor:

$$W=n\,T=\frac{e\,(E-e)}{R+r_m}$$

This is usually called the activity. Differentiating this we have

$$n\frac{dT}{dn}+T=\frac{1}{R+r_m}\left(e\frac{dE}{dn}+E\frac{de}{dn}-2\,e\frac{de}{dn}\right).$$

or substituting for T its value in terms of E and e and rearranging, we have for our fundamental equation:

$$\frac{dT}{dn}=\frac{1}{n\,(R+r_m)}\left(e.\frac{dE}{dn}+(E-2e)\frac{de}{dn}-\frac{e(E-e)}{n}\right).$$

Let us examine the case of a shunt motor supplied with a constant current K, and writing as before:

$$K=\frac{E}{r_s}+\frac{E-e}{R},$$

and assuming that the magnets are far from saturation, we have:

$$e=\text{const.}\times n\,N\frac{E}{r_s}=C\,n\,N\frac{E}{r_s};$$

N being the number of turns of wire in the shunt magnetizing coils, and C a constant. Solving for E and e, we obtain:

$$E=\frac{-r_s\;RK}{CnN-(R+r_s)};\quad e=-\frac{CnNRK}{CnN-(R+r_s)}$$

$$\frac{dE}{dn}=\frac{r_s\,RKCN}{(CnN-R-r_s)^2};\quad \frac{de}{dn}=\frac{CnNK(R+r_s)}{(CnN-R-r_s)^2}.$$

Substituting these values in our previous equations, there results:

$$\frac{dT}{dn}=C^2N^2RK^2.\frac{CnN+R-r_s}{(CnN-R-r_s)^3}$$

an equation of the second degree in n, and representing the rate of change of torque. As R is too small to affect the sign of the fraction, it follows that $\frac{dT}{dn}$ is always positive; that is, the torque increases as the speed increases.

Furthermore, as $\frac{dT}{dn}$ is a function of n, the speed, the rate of change depends upon the speed itself, being greater for low speeds than for high speeds. However, the equation is only true within a limited range, for at great speeds, the magnets would be saturated, though the armature reaction would practically change but little.

If we now regard E constant and suppose the motor to be a series motor, we have:

$$e=CnM.\;\frac{-e}{R};$$

M being here the number of turns in the series magnetizing coils. This may be written:

$$e = \frac{C\,n\,M\,E}{R + C\,n\,M}.$$

From which we obtain:

$$\frac{d\,e}{d\,n} = \frac{R\,C\,M\,E}{(R + C\,n\,M)^2};$$

and substituting as before, we have at once:

$$\frac{d\,T}{d\,n} = -2\,\frac{C^2\,M^2\,E^2}{(R + C\,n\,M)^3};$$

which is of the third degree in M, but negative. Hence, the torque diminishes as the speed increases, and as before $\frac{d\,T}{d\,n}$ is different for every value of n.

Suppose, now, that we have a series motor supplied with a constant current K. Here,

$$e = C\,n\,M\,K \text{ and } \frac{d\,e}{d\,n} = C\,M\,K = \frac{d\,E}{d\,n};$$

$$\frac{d\,T}{d\,n} = \frac{1}{R\,n}\left(E - e\left[\frac{d\,E}{d\,n} - \frac{e}{n}\right]\right) = \frac{1}{R\,n}$$

$$= [R\,K\,(C\,M\,K - C\,M\,K)].$$

Or,
$$\frac{d\,T}{d\,n} = o.$$

That is, the torque being independent of the speed is a constant. Finally, let us consider the case of a shunt motor on a constant potential circuit. As before

$$e = C\,n\,N \times \frac{E}{r}; \text{ and } \frac{d\,e}{d\,n} = \frac{C\,N\,E}{r_s};$$

and by substituting and rearranging, we have:

$$\frac{d\,T}{d\,n} = -\frac{C^2\,N^2\,E^2}{R\,r_s^{\,2}} = -\text{ constant.}$$

In the last two cases, therefore, the rate of change of torque with speed is a very simple expression. For a shunt motor supplied with a constant potential current, the regulation may be excellent, provided $\frac{d\,T}{d\,n}$ is a large quantity, but in no other cases have we even an approximate regulation. For constant current work we require a series machine, and the best method of regulation to be applied to it, so far devised, is a mechanical governor, which automatically changes the number of ampere turns in the field corresponding with the load on the motor. Such a governor need waste but little energy and may be as continuous in its action as desired.

Of the losses which occur in motors, we have in all cases to take account of those which are due to the following causes:—

First.—Heating of wires equal to:

$$C^2\,R \text{ or } \frac{E^2}{R}.$$

Second.—Foucault currents in pole-pieces:

This depends upon the number of armature sections; that is, fluctuations of current, and is generally small unless the Pacinotti form of armature is used.

Third.—Foucault currents in armature. This depends upon (strength of field)^2, and in the modern laminated armature may be neglected.

Fourth.—Reversals of magnetism of armature equal to $\frac{1}{4\,\pi}$ (coercive force) $\times$ (maximum induction) $\times$ n $\times$ (volume). That is, it depends upon (strength of field)^2 and velocity of rotation. No amount of subdivision of armature core can affect this, except in so far as it modifies the total volume of iron in the armature. However, a low-magnetic resistance is necessary, and to secure this the armature must contain much iron. It is on this account that an advantage from a stationary armature core would be derived

Fifth.—Momentary short circuiting of armature coils, depending upon coefficient of self and mutual induction of armature coils and strength of field.

Sixth.—Finally, friction in bearings. This is difficult to estimate. If the belt is such that Morin's principle holds true, losses due to friction are constant.

In self-regulating motors, the speed is constant or nearly so; hence, the causes of the dissipation of energy are confined to variable currents in the conductors and to changing field strength.

These in compound wound and constant current motors depend upon the load, but as we see at once are practically constant for a properly made shunt machine. For a pure shunt machine, therefore, the efficiency, provided the speed does not change, is independent of the load.

Before bringing to a close the few remarks which I have ventured to make on the subject of electric motors, it may be interesting to give a few facts regarding the growth of motor industry, and to point out how various are the demands made upon these machines for manufacturing and commercial purposes.

Through the kindness of the Executive Committee of the National Electric Light Association, I am enabled to bring before you a few figures which will, I trust, act as an incentive to increased activity in this direction.

The committee has addressed circulars to 234 companies engaged in electric lighting with the following questions:

1. Number of motors in operation.
2. Size of motor.
3. Maker's name.
4. Current used.
5. Charge per h. p. per month.
6. Charge per month per arc and incandescent lamp.
7. Results as to service.
8. Customers' opinions as to power and service.

As a result, answers have been received from fifty-six companies, and from these replies the following statements have been gathered.

Average charge per h. p. per month, 10 hours run..	$10.00
Average charge incandescent lamp, 10 hours run....	13.50
Average charge per arc lamp until 10 o'clock.......	9.83
Average charge per arc lamp until 12 P. M..........	13.00
Average charge per arc lamp all night..............	22.00
Highest charge per h. p. per month.................	15.00
Lowest charge per h. p. per month..................	6.25
Highest charge per incandescent lamp per h. p......	21.00
Lowest charge per incandescent lamp................	11.25

The motors supplied with current have been used for the following purposes:—driving ventilating fans, collar and cuff machines, printing presses, various apparatus in repair shops, sewing machines, coffee mills, machines in gun shops, sausage machines, elevators, lathes, pumps, dams, ice-cream freezers, organ bellows, appurtenances in laundries, etc., etc.

Sizes of motors have ranged from ½ to 15 h. p. 26 companies have supplied motors from arc light circuits; 14 from arc and incandescent, and 16 from incandescent lamp circuits alone. In 34 cases, subscriber owns motor and pays per month for current. In other cases, companies own motors and charge rental for same.

Companies are endeavoring to have subscribers own motors in all cases, and pay for the current. Electric light companies are satisfied and willing to enlarge the business. Customers' reports are also very satisfactory.

Although the number of cases cited above is small, it is still enough to show us how effectually the motor can supplant the steam engine, especially for those purposes for which the power required is small and under complete control. The opinion of those who have used electric motors indicates that they do their duty well, and encourages us to expect a brilliant future for this branch of applied electricity.

ECONOMIC VALUE OF STEAM PRESSURE RECORDS.

BY JARVIS B. EDSON, M. E., OF NEW YORK.

THE engineer of the present century begins his operations based upon the pressure of steam he is capable of maintaining in his steam boiler. From this he extends his calculations and elaborates his plans for the prosecution of his work. It matters not what the problem may be, whether it is the grain to be threshed, grist to be ground, hills leveled or mountain pierced, ore raised or office reached, ocean plowed or continent crossed, the same agent performs them all. The tropical fruit while rushed to a northern market is also cooled by it, and the plethoric meat of the western plain is refrigerated during its transcontinental run, till finally we see the coal transformed into heat, then into steam and manifesting itself in work, in its production of coal exemplifying the beautiful law of the conservation of energy and making us thankful for the birth of steam. At present the civilized world is lighted by it and searching for one greater than Faraday who shall give us a substitute and sound the death knell of steam. So, meanwhile, we reconcile ourselves to the loss passing up the chimney and stand aghast when the boiler "lets go," scattering death and destruction in its wake, and simply conclude with a verdict of "nobody to blame."

Investigation and scientific study have done much however, both for the construction and the safe and economical management of steam boilers. Mystery no longer accounts for boiler explosions, for the conclusion has been reached that "the cause of

such accidents can be wholly prevented and controlled," and ignorance is becoming dethroned in her management, to make way for the more intelligent methods of boiler management. The men from our colleges and technical schools demand the facts that they may proceed to their conclusions intelligently. Not theirs, to view the 135 victims of a "Westfield" explosion, with "nobody to blame," for it is not they, who beat upon pans and blow horns to scare the "devil" when the sun darkens. The solar eclipse to them was calculated upon and predicted in advance of its coming. Their verdict will always be: somebody is to blame, explosions are caused by ignorance or neglect.

And so with economy, for to them, the furnace will be a sort of gas retort, and the burning of coal a scientific study. To them, the boiler, a giant struggling against almost equal odds, harrassed by conflicting expansions and contractions, constant and varying strains, attacked by corrosion and injured by scale. They will know it is a magazine of enormous power in which each cubic foot of water has the explosive energy stored within it of a pound of gunpowder, and to them eternal vigilance will be the price of safety. Certainly then it does appear strange, that for such a charge we should employ cheap labor, that the most ignorant man about the establishment is the favorite fireman. For my part it is incomprehensible how either practical men, or those of the usual business sagacity can feel willing to discount the chances against such a course.

Nevertheless, the engineer of to-day is confronted with these conditions, and the safety and economy of his "plant" become of imperative importance to his success. In these two connections then, I desire for a few moments the indulgence of your attention, with a view to submitting to your judgment, certain facts bearing upon the importance of providing some method whereby a surveillance over the steam pressure may be had, for accurate and full information as to the management of our boilers should always prove useful and interesting.

Upon the question of safety, it requires no demonstration to prove that whatever impairs the boiler's strength or durability should be prevented.

To make such prevention possible, however, presupposes the means whereby the preventable occurence may become known. If, therefore, fluctuating or excessive steam pressures are injurious, how are we to be made aware of their occurrence?

Obviously but one method exists, and that is the resort to automatically steam written records of them, and from which we can determine the departure from conservative limits. Assuming that the ordinary steam gauge, which only indicates the pressure, at the instant, is entitled to the great confidence bestowed upon it, it undeniably lacks the ability to afford us any more information, as to the pressure of the previous moment than the proverbial dead man, who can tell no tales. In fact for many years, owing to sharp competition they have been so poorly constructed as to be even dangerous to use—so liable are many to rely upon them for the determination of the pressure they are at the time carrying, even going so far as to adjust their safety valve weights to blow with the gauge. The dials are first produced by different methods in large quantities, all alike, and the springs taken afterwards, which will come the nearest to the "travel" called for by the dial so laid out, whereas, each spring has its own "travel," and its dial should be laid off accordingly, and a suitable price demanded for the article when made, as a cheap and unreliable steam gauge is dangerous, and dear at any price.

When, however, only one of these is relied upon for 20 years, it is apt to be considerably out. Last month I came across one such, in a state hospital which was ten pounds out, and in which case the pipe leading to it was stopped up by dirt, etc., so the pressure rose and fell not with the pressure, but soon after change occurred, as the condensed steam "water" could soak through the obstruction.

Instead, therefore, of relying solely upon the ordinary indicating instrument, whether it be entitled to such confidence or not, common prudence would dictate the employment of more than one gauge, and preferably that the supernumerary should be a recording machine.

The records of steam pressure carried have a large prudential value, for the reason that with their use a fireman must give up his position or do what he is required. For instance, if a careless man lets his steam get too high before he discovers it, and the safety valve does not blow as calculated upon, from any of the causes common in such cases, who other than the fireman will be any the wiser, and when will the remedy for a careless fireman, or faulty or overloaded safety valve be applied.

It is generally supposed to be necessary to first know of a trouble before its remedy can be either determined or applied.

The only way, therefore, to know whether one's boilers are being exposed to excessive pressure or not, is to use a gauge which records the pressure.

Occurrences are constantly taking place under that smooth sounding term "banked fires," which would electrify every hair of one's head if revealed to those who have so much at stake, and think such a fire harmless. A strong fire towards stopping time leaves the boiler setting so hot as to supply sufficient heat for running up the pressure beyond what a cold setting could do. Yet when the fires are once "banked" the man "lets up" on his watchfulness, and generally the boiler is left entirely alone for a long interval. "We never carry steam at night as we 'bank' our fires, and in the day-time have a good careful man around," is an expression common to most steam users, but a few moments will generally convince them that they have assumed a very ridiculous and untenable position. The police of our cities frequently find steam blowing off from boilers under the sidewalk during their night perambulations, and have learned that it means one of those places where they "never carry steam at night," and he routs somebody out in the building or neighborhood to remedy the trouble. One summer, recently, while stopping in a manufacturing town, I heard a shrill whistle blow for two or three hours during the night, and concluded, as I learned the next morning, that it was a low water alarm. The police hunted up an engineer to go to the establishment and give the boiler some water, and fortunately the boiler took the engineer's proferred kindness without getting up and going off and out of shape about it, either.

A case occurred last October, under one of the costliest buildings on Broadway, New York, where fires are "banked" and they "never carry steam at night." It appeared, however, from the recording gauge chart, the next morning, that something had caused the recorder to make a high steam line from a good part of the night, and investigation proved that the night watchman heard a roaring noise when in the top of the building, and concluded that it must be the boiler "blowing" about something, so he clambered down twelve or thirteen stories and found the damper closed and a full pressure on. Of course, it goes without the saying, that if the valve had been fast in the seat, or the weight shifted on the lever from any cause, a first-class explosion would have followed. The boilers are provided with an approved pattern of damper regulator on the main flue, and also have individual dampers on the branches from each boiler leading into the main flue. The individual dampers are of course for shutting off either boiler when not in use. The trouble was caused by the fireman not knowing enough, or forgetting to unhook his automatic regulator connection before leaving for the night, and so when the banked fire and heated walls had radiated sufficient of their heat the pressure of steam closed the damper, and the heat being entirely shut in and no air passage left open to the chimney, and little or no steam being used in the building, "safety valve" was called upon and fortunately did its duty and prevented the steam passing beyond the limit as shown by the chart.

In the same establishment, only two months later, on New Year's morning, the night watchman closed the furnace doors at the usual hours, so the fires would be in better condition for the day fireman when he arrived, but the day man did not arrive until some two hours later than usual, as it was a holiday, and so the steam went up again and startled the neighborhood with the racket for an hour or so. The day man claimed that he told the watchman not to close the doors until a later hour, which the latter denies. Be it all as it may, in both instances the chart, daily submitted to the manager of the property, revealed the occurrences, and brought forth an investigation, resulting in more correct methods of transmitting orders and causing the unhooking of the regulator while under "bank fires," and also in making the night watchman make more frequent visits to the boiler room. Who can deny but that in this instance, their indifferent methods would ultimately have resulted in exploding their boiler had not the recording gauge unmasked the facts and caused the proprietor to set some needed rules in force. If an ounce of prevention is better than a pound of cure the instrument repaid its first cost in these two instances alone.

Self interest should suggest the use of such a safety appliance particularly, inasmuch as all persons are supposed to intend the natural consequence of their acts, for proof of an act, or course of procedure, which was adopted or persisted in to deceive the public or in defiance of its safety, is sufficient proof of the intent to deceive and jeopardize, unless the doer establishes innocence of such intent and knowledge, and the burden of proof rests on him. If, therefore, it be true that no steam boiler "plant" can be conducted as intelligently, economically or safely, without the information and aid supplied by the pressure recording instrument as with it, then proof of negligence can be made out establishing the fact that such a valuable monitor and means of information as the pressure recorder had been rejected, and failure to secure such competent attention may be properly urged in courts of law as evidence of negligence.

Even so important a matter as the amount of pressure applied by an authorized inspector in testing a boiler with hot water, has shown that only an excess of eight pounds was put upon an old boiler which is regularly carrying from 55 to 60 pounds pressure of steam. The record further shows the pressure to have been "jumped on" for an instant and then released, allowing no time for inspection while under the testing pressure of the seams, etc. No satisfactory reason has been obtained so far, for this improper method of testing, but the fact has been established, and so much gained. Certainly more confidence could be reposed in a test where the record shows that the boiler sustained the testing

pressure for five or ten minutes, and during which time the testing engineer could be presumed to have been examining the boiler for evidence under such strain.

Another matter revealed frequently by the recording gauge chart is the habit indulged in by many attendants, called "bottling up steam." The most frequent occurrence of such habits takes place at a few minutes before starting time in the morning, and at noon, and in some cases, just before cleaning fires. Of course, such prejudicial habits are the simple outgrowth of ignorance, concerning the limited amount of steam quantity they can bottle up, and the very small service it can render, compared with the injury such practice, when persisted in, ultimately does the boiler. Aside from this objection, the habit is exceedingly pernicious, because only a few moments neglect would cause the pressure to accumulate, to the point at which the safety valve is supposed to open; then, if it happens to be inoperative, an accident is almost certain to follow. No excuse should be taken in any shape, under any kind of reasoning, for "bottling up steam;" if the generating capacity of the boiler is not equal to the current demand, it cannot be helped by simply bottling up; in fact, it has been my experience that where the record line has been extremely crooked, upon the first introduction of the recorder, the effect of such record has been to cause a much more uniform use from day to day, until the nearest approach to uniformity has been reached, consistent with the vicissitudes of the demands for steam. A steam user once apologized for the appearance of his record, saying that the steam was drawn from the boiler at irregular periods by persons in the mill, and consequently the fireman could not carry any very regular line; that his use of steam was different from that in most places, etc. Noticing, apparently, my incredulity, he asked if I disagreed with him. My reply was "Do you suppose that the steam necessarily falls as low as this record indicates?" In other words, I called his attention to the fact that where a fireman is on the keen lookout for his boiler pressure and water level, he will readily detect the pointer hand of his gauge the moment it begins to rise and fall, and govern himself accordingly. For instance, if he sees the hand indicating that the pressure is falling, he will avail himself of the opportunity to slow down his feed, and perhaps open his damper wider, and if his fires are in prime condition, withold fresh coal for a few moments, then when the onslaught upon his boiler has ceased, and the hand of his gauge is stationary, or starts to move upwardly, he will at once set about to replenish his coal and water, and so have his conditions favorable in a few moments for another attack upon the steam supply. When his steam is raising he can afford to feed and to fire, and his thought should be to have everything in prime condition while he has surplus power and opportunity. Then he would not be caught so badly when these extreme attacks were made upon him. The cause of these extreme fluctuations then, is largely due to the fact of his being unprepared to meet these emergencies, and becoming alarmed when his steam has fallen 20 or 30 pounds, he attempts to get it up by replenishing his fire, as it seriously needs it, with coal, which only tends for the time being to reduce the pressure still more until it has been capable of delivering its gases, ready for combustion. After this little explanation, the proprietor shook his head, and said he had never thought of it in that light, and that he would have to call John to him and have a talk with him. Now the result of this was from that time on, the man's record never fluctuated in the same manner again, and the average steam line maintained was one which showed constant attention to firing frequently in small quantities, and keeping himself in shape to meet these emergencies.

Undoubtedly, the man had to work a little harder at first, but afterwards it was easier when he properly understood the matter and manipulated his fires accordingly. The suggestion to the proprietor was exceedingly valuable. It resulted in the proprietor teaching his man, and mutual regard between them afterwards, because it showed that the man was capable of being taught and also willing to be, and that the proprietor had evidence of the resulting fidelity. The dissemination of knowledge among firemen can certainly do no harm, and when it reaches a man who desires to hold his position and give satisfaction, it will do much good. Men uneducated to the science and what constitutes firing steam boilers, can hardly be expected to use that knowledge which others possess professionally.

Some men will fill a furnace full of coal, so as to have more time to walk around; then after a time up goes the steam pressure, because more steam is generated than is wanted; more heat is generated than is wanted; then the feed water is turned on and the water level run up so as to keep the steam pressure down; the safety valves may blow, or not; the damper is closed; the fires smolder; large quantities of carbonic oxide gas generated up the chimney—and this means an escape of unconsumed fuel, which means dollars and cents. After a while, the fires burn lower, and down goes the steam, helped down, it may be, by another dose of coal, and so we can imagine the final effects on boilers used in such a manner. The position of a fireman may be considered an humble one by some folks, but he is a man for all that, and his pride in what he can do is a stronger spur than anything else. Let him see that you care for what he is doing, and take a careful interest in his work, and let him understand furthermore that his own grading depends upon himself, as established by his records; then you are in a fair way to have confidence in your man, and in your safety, and also feel assured of economy of fuel. But eventually you must pay him what he is worth. If not, some one else will be glad to have him. Suppose for instance, a man who burns three tons a day, is paid two dollars for such service, and in so doing he is wasting as little as 10 per cent. If coal costs $4.50 per ton, the loss will be $1.35 per day, or what is equivalent to paying a man $3.35 per day, who can save this amount; but when amounts of, say, 8,000 tons per month are used, the saving of only 10 per cent amounts to $80 per day, and the small portion of which is offered as a premium to the men who use this coal would go a long way towards saving the remainder of this money. What is wanted is the maximum of steam per dollar's worth of coal; much can be saved by the manner of its use, and it is within limits furthermore to say that, from 5 to 10 per cent, is frequently gotten rid of by firemen not qualified as such and entirely ignorant or indifferent regarding the science of complete combustion. Certainly it is of vastly more importance to a proprietor, both on the score of safety and economy that his fireman shall be a man trained in the art of properly burning the fuel supplied him, than that his engineer shall know, particularly if the latter does not impart the information to the fireman. The practical value, therefore, of the steam record is in this connection that it compells the fireman to give close attention and maintain uniform water level; and uniform steam pressure cannot be had with anything short of the closest scrutiny of the steam gauge, which means economy of fuel and safety as well. The explanation of the charts has given much information touching unexpected occurrences but innumerable other instances might be cited which would only tend to exhibit the surprisingly large number of them possible wherever steam is used, and those facts become more generally known to those who are not at present deriving the information from such instruments. They will be extended, and more careful methods of caring for steam boilers under pressure will be inaugurated ultimately, resulting in not only greater economy of fuel, but in a greater degree of immunity from those disastrous explosions which destroys so many lives and so much property annually.

WHAT CONSTITUTES A GOOD CARBON POINT.

BY G. W. PARKER.

FROM the standpoint of the manufacturer all well baked carbons that are straight, free from cracks and other similar defects, and made from pure material, are good carbons. The electric light engineer will say that no carbon is good unless it will centre properly and give him a reasonably long life with a good light. He is not at all inquisitive as to the method of their manufacture, provided they give such results. But as the manufacturer can go no further than to correct any errors in his mechanical processes, the value of the carbon afterwards depends upon the conditions of its use. Such carbons as are described in the first paragraph will in some currents be satisfactory both as to light and life. In others the light may be brilliant and the life too short, or there may be arcs too short or too long, flaming, or other defects arising from the unsuitability of the carbon to the current, there being no inherent defect in the pencil itself. Therefore, to cover the whole ground of this important inquiry, we should also have the carefully compiled statements of your experience of the behavior of carbons burning in your lamps under varying circumstances. From this, results of great value to both sides might be obtained.

There appears to be no trouble in determining what constitutes a good carbon mechanically, but to you a good carbon means one that will give you satisfactory results in your use of it, and there we find several difficulties, without taking into account imperfections in your apparatus. The first is the difference in the strength of the current used in the different systems, and, also, in many cases in different plants of the same system, the corresponding differences in the resistance of each lamp, and frequently, unequal adjustments of lamps in the same plant.

For convenience we are in the habit of referring to those systems in which a small current and a long arc is used as high tension systems, and those in which a large current and short arc is used as low tension systems. The requirements of the low tension seems to be a carbon that is hard, well plated, and a good conductor, the latter being the most important. In the high tension, on the contrary, hardness and conductivity seem to be of secondary importance. There is a tendency to flame and burn unsteadily when a hard carbon is used in these systems, and a softer one sometimes becomes necessary, which in many cases shortens the time in which a lamp will burn without being retrimmed, but, in such case the difference is fully made up in the brilliancy of the light. On the other hand, where a soft carbon is burned in a low tension current, the tendency is to form needle points which prevents the carbon from centering properly, causes them to heat, and is apt to burn the holder.

Let us pursue the inquiry touching the questions of size, con

ductivity, mortality and light, and ascertain if definite relations can be established in regard to them that may result in guiding us to the selection of perfect carbons for use from a mass of mechanically good carbons.

It is a matter of great interest to know in what manner and to what extent the size of the carbon affects the result in a current of given strength, covering, of course, in the general question of conductivity, the all-important results of light and life.

It is well known that a hard carbon offers less resistance to the current, or, in other words, has greater conductivity than a soft one; therefore, in carbons of the same length and diameter, made of the same material, by the same process, conductivity increases and diminishes respectively with their hardness and softness.

In either hard or soft carbons whatever of conductivity they possess respectively will be increased or diminished as their diameters are increased or diminished, the length being maintained. It would appear, therefore, that it is possible to make a softer carbon of larger diameter that will be the equivalent, in conductivity, of a harder carbon of smaller diameter.

Of carbons of the same *hardness* and length, but having different diameters, the larger will, undoubtedly, outlive the smaller. Of carbons of the same *diameter* and length, but differing in hardness, the harder will outlive the softer. Therefore, a carbon of larger diameter which is soft, may be equivalent to a smaller carbon which is hard, as to life, just as it has been shown to be equivalent in conductivity. The life of a carbon is, of course, dependent upon many vicissitudes, such as high winds, broken globes, etc.; but under the same conditions the statement made above is, undoubtedly, a fact.

It is well known and admitted that as between hard and soft carbons of the same diameter the latter will give a more brilliant light. It is just as well known that in case of hard carbons those of smaller diameter will, within certain limits, give a more brilliant light than those of a larger diameter. On the above statement of facts it may be regarded as settled then that with the same diameter, but differing in hardness, the hard carbon will possess greater conductivity and have a longer life, but with less brilliancy of light; while the softer carbon will have less conductivity and a shorter life, with a more brilliant light. And, further, that with uniform hardness, but differing in diameter, the larger diameter will have the greater conductivity and longer life, with a less brilliant light; while the smaller diameter will have less conductivity and a shorter life, with a more brilliant light.

The foregoing statements indicate invariably that with greater conductivity light diminishes and life increases; and, conversely, that with diminished conductivity the brilliancy of the light is increased and the life shortened. In corroboration of this it appears that a small, hard carbon is, practically, the equivalent of a larger, soft carbon, their conductivity being also equivalent.

Heretofore, it has been considered probable that the diameter, candle power, resistance per lamp, conductivity of the carbon point, and strength of current, are all interdependent, and a change in any of them will affect all the others, requiring a counteracting change or adjustment in some of them, in order to restore the proper relations between them. This, if so, you can readily see is difficult to do; for part of the work is to be done by the manufacturer, and the remainder is under your control. On the other hand, if the deduction can be properly made from the statements herein presented, that the resistance of the carbon point will determine its capability in respect to light and life in the different currents, the trouble is practically removed. It is not impossible, I think, to construct a machine that will, at no great increase of cost, assort the carbons into groups of uniform resistance or conductivity. Then, with constant currents, clean lamps, perfect connections, and insulation, you will ascertain practically that carbons mechanically good will prove to be good and uniformly so in actual service.

Much more could be written upon this interesting question, but this paper is already too long. I have noted for your discussion some important points which I hope your experience will enable you to determine definitely if they are well taken or not. I would be glad to have the whole question of the imperfect burning of carbon points thoroughly canvassed, so that manufacturers would get some hints as to what may be done by them in the way of correction when the fault lies at their door. It is especially desirable to be informed if that very disagreeable feature in the burning of carbons called "flaming" is always the effect of one particular cause and what that cause is.

LEATHER BELTING—ITS ORIGIN AND PROGRESS.

BY CHAS. A. SCHIEREN.

In the early part of this century the first attempts were made by English machinists to transmit power by means of bands or straps made of leather; this transference of power from one line shaft to another, needed a peculiar quality of material, one that combined pliability, solidity, and strength, and leather was the only known substance which suited that purpose. Many experiments have been made since then with other materials such as rubber textiles, wood, paper, and even iron and brass; also belts woven of horsehair, etc., but none have been able to supersede leather, and even to this day it is universally acknowledged that

"That there is nothing like leather
When well put together."

Belts made of leather are given the preference wherever they can be used, and it is somewhat strange that the machinery world of to-day know so little about the origin, progress and growth of an article that plays such an important part in the transmission of power, as leather belting.

For the benefit of those who have not read up the history of belting, I will give a brief account of the development of its manufacture in this country, and it will then be seen that this branch of trade has kept steady pace with this progressive age. Previous to 1820 and even up to 1835, much of our machinery, which then consisted principally of looms, etc., was imported from England and had all the necessary belting sent with it. These belts were made in a very crude way, generally from heavy leather and were cut across the hide, so that all the laps or joints were from the belly part of the hide. These parts were lapped over from six to eight inches and were not cemented, but were sewed together along the edges with white alum-tanned leather, similar to lacing; then large heavy rivets were put in the centre, and the whole thing made as clumsy and as heavy as possible.

In those days machinery was run at a very low rate of speed, the belts had to bear a severe strain, and therefore generally proved unsatisfactory; so much so, that machinists became discouraged and used gear wheels and upright shafts instead of belting. Upright shafting was largely used in flour and other mills where heavy work is required, as late as 1860.

Belt making up to 1840 was hardly known. Leather dealers and curriers, it is true, kept some extra dressed leather on hand for belting purposes, which mill owners and saddlers bought and made up into belting. All this stock was neither selected nor stretched, and the quality of belting it made can easily be imagined. In 1842, Wm. Kumble commenced the manufacture of leather belting at 33 Ferry street, New York. He also had a tannery in Frankfort street, where the bridge stores are now located. The foreman of this tannery, Mr. Fred. Wood, an ingenious and enterprising mechanic, invented some of the machinery necessary to stretch and join a belt in order to make it run smoothly, evenly, and straight. Mr. Kumble gained quite a reputation at this, his new enterprise, and it was not long before he had several competitors. Thus belt making became a distinctive and separate business, and before long, through Yankee push and ingenuity, we manufactured a belt in this country which was far superior in quality and workmanship to any made in Europe. Since this we have not lost our advantage, but on the contrary have made such great strides in this line of business, that to-day it is universally acknowledged that the United States turns out the best belting in the world, and American belting is as much sought after in England and France as the Peep O'Day Yankee Clocks are in England.

European belt makers are striving to imitate our methods of making belts, and for this purpose purchase our improved machinery, with which they hope to make a cheaper belt of equal quality, and thus drive out American competition.

However, I must return to my subject. My first illustration shows the method first employed for making a joint. This was, of course, found to be very deficient and soon an improvement was made which consisted in champfering the end of the under lap, which came in contact with the pulley, so that the belt was much smoother and better.

Waxed thread was used to sew the belt, and light rivets were used in the construction, which made it run easier, but as the leather was not stretched, the belts would stretch all out of shape and the pulleys had to be flanged in order to keep them on. Not until Mr. Wood conceived the idea of stretching leather before being cut into belting, was this trouble entirely obviated and a flange on the pulleys no longer needed.

The inventions of Mr. Wood, however, are now superseded by more valuable improvements which supply the present demand for perfect running belts, and the belts of to-day are as much superior to the belts of Mr. Wood's time, as is the steam engine of to-day, to the steam engine of 1840. When Mr. Goodyear invented belts made of vulcanized rubber, everybody thought that they would in time supplant leather. Rubber belting offered great advantages, being cheaper and made without joints, perfectly even and smooth, and apparently run much easier. However, many disadvantages were detected by actual use, and very soon rubber belts took their particular place in the use of belting, and are now manufactured in very large quantities; but for all swift running machinery leather is absolutely necessary and most reliable, and generally preferred.

During the war the demand for belting increased enormously, and it taxed the facilities of the belt makers to supply the demand. This made them somewhat careless and the quality of belting greatly deteriorated. The aim of the belt makers seemed to be, how much of the hide they could put into belting irrespective of quality. At this time, Mr. Underwood invented a method of making belts of pieces of leather six to seven feet long.

He put short laps at both ends and covered the thin and flabby neck leather with splits which made them even with the butt ends. These belts proved to be total failures, and were soon abandoned. Mr. Underwood, however, made many other valuable inventions; his well-known copper shank rivets and burs, placed on the ends of laps to prevent them from raising, are still used by some; and his patent angular belts created quite a sensation when first introduced. The latter was a novel and ingenious invention. Great power could be transmitted with narrow angular belts, but they have outlived their usefulness and are now supplanted by other later inventions.

In the midst of this great demand for cheap belting, Mr. Joseph B. Hoyt revolutionized the trade by going to the other extreme. He gave orders that all of his belts should be made with short laps only, that the butt end should be joined to the shoulder lap, to accomplish which the whole shoulder had to be cut away. He ordered also that only 36 inches of the centre of the hide should be used, and that every width of belt should be stretched by itself. This was a most radical change and startled the trade, while it gave Mr. Hoyt a world-wide reputation for belt making, which he held until his retirement from business with a large fortune, a few years ago.

Mr. J. B. Hoyt deserves credit for having established a *standard* for belting which is reliable and cannot be surpassed, unless indeed the nature of the steer hide changes. The trade everywhere has been compelled to adopt this method of making belts, because customers have been educated up to it, and many of them will buy nothing else.

About 1865 our manufacturing industries developed to an enormous extent, and immense factories were erected which required engines of great power, that could transmit from 500 to 1,000 h. p. This created a demand for very wide main driving belts, and great difficulty was experienced by belt manufacturers in making wide main driving belts over 36 inches which would be of uniform solidity and equal tension. Whole hides contain on an average 36 inches in width of solid leather, and never exceed 45 inches, while orders come in from all sides for main driving belts from 50 to 75 inches in width. Ever since this time experiments have been made on wide belting, and to-day we have reached such a state of perfection that leather belts of any desirable width can be constructed.

A main driving belt is now generally made on the following plan: Take for instance a double belt six feet wide. (See illustra-

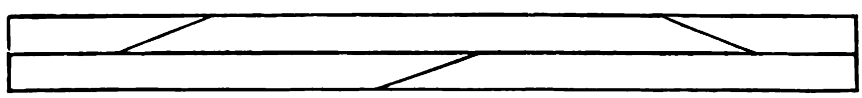

FIG. 1.—Diagram Showing Parallel Seam or Joints for Wide Belts.

tion.) The lower or running part of the belt consists of two pieces of leather of equal widths, cut from the centre of the hide and joined together parallel; then a 36 inch piece is placed in the centre of the lower two belts, and two end pieces filled out to the required width, and all joined with parallel joints. This makes a belt of uniformly solid leather and equal tension, and one which is bound to run perfectly smooth and straight. Powerful stretchers have also been invented which can take in any width of leather.

Alexander Bros. patented a method by which they can use side leather and accomplish the same result. However, they do not make a parallel joint, but simply butt the pieces together, as above shown, and then cement and rivet the same.

Eastern belt makers were the first to produce a light double belt with neither rivets nor other fastenings, claiming that rivets

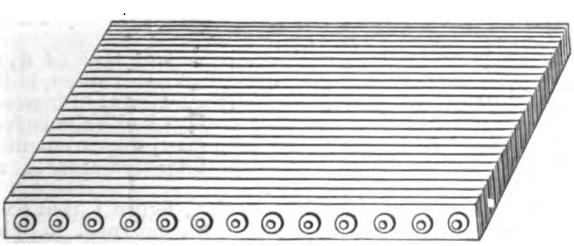

FIG. 2.—Edge Cut Leather Belting.

and burs were not necessary if a belt was properly cemented. They were used for machines running at a high rate of speed.

About 1864, L. N. Clark, of Boston, Mass., made that line of belting a specialty. He produced a belt which would probably find great favor to-day for running dynamos. His method was to split the pieces of leather to a perfectly even thickness and then cement them together. This made a double belt, rather thin, but well calculated for high speed. Mr. Clark retired from business about 10 years since.

Many experiments have been made to combine textile materials and leather in the manufacture of belting. In 1872, Messrs. Clark and Slemmer, of Philadelphia, patented a belt of this kind. Their method was to stretch a heavy piece of cotton duck of the width required, and place it between two thin pieces of leather of the same width. This made a strong belt which at first was received favorably by the trade, but which in the end, did not wear well because there were two different kinds of material used; the cotton would stretch more than the leather, or vice versa, and the belt would very soon work itself loose, and the cement and rivets break. Very few of these belts are in use at present. Another method is used which was patented by T. Thompson, of Cincinnati, and which is now manufactured by an eastern concern. In this process, as in the other, a heavy cotton duck is stretched, a thin layer of leather splits cemented over its surface, and then the two sewed together.

These belts are used to some extent on dynamos. Their main weakness, as already stated, is the unequal stretching qualities of

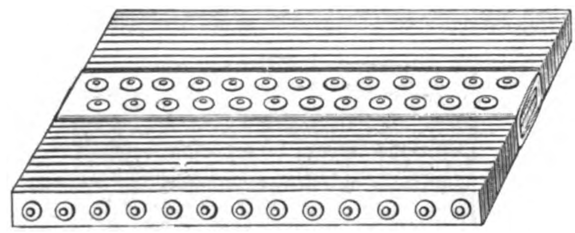

FIG. 3.—Edge Cut Belting (Howe's Patent).

Shows a device in the centre to make the Belt conform to the rounded face of the pulley.

the two materials used, but this objection is not so marked where thin pieces of split leather are used, as above described. The atmosphere, however, exerts a great influence over these belts, and they contract or expand with heat or cold, and cannot therefore be recommended except for easily adjustable machinery. Numerous other patents have been devised but are of minor importance.

Edge Cut Leather Belting.—These belts are hardly known here but are largely used in England for running machines where slow, heavy and positive motion are required, and they do excellent work.

These belts are made in the following manner: The leather is dressed and stretched the same as for ordinary belting; it is then cut into strips one inch wide and holes punched at distances of one inch from each other, to admit of steel bolts being inserted. These strips are then placed side by side until the desired width is obtained, when they are bolted and riveted together. This makes a belt which is rather clumsy, heavy and stiff, but one that can stand more strain and hard work than any other belt made, and is very powerful.

This audience, however, is probably interested more in the progress and improvement made in leather belting for special

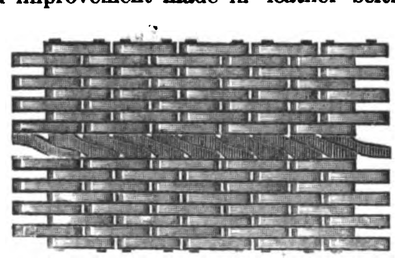

FIG. 4.—American Patent Joint.

use on dynamos and electric light machinery, than in the progress made in any other branch of the trade. I shall therefore describe different styles of leather belts which have met with great success in this field.

When the electric light first came into use, electricians found it exceedingly difficult to get a belt suitable to use on dynamos. All of the belts which they tried seemed to lack something, and ofttimes the heaviest and most carefully made leather belts failed to do the required work. This problem received special attention by some of our most enterprising belt makers, and various methods for making these belts were introduced with more or less success. About five years ago, the writer experimented on producing a belt which would be particularly fitted for transmitting power when run at a high rate of speed. I considered the stretching process of leather for dynamo belts the most important, because the steer hide by nature forms a peculiar shape, having fine and solid fibres on the back and then rounding off towards the belly with loose coarse fibres; to get therefore a perfectly flat piece of leather of even tension from the centre of the hide needs the utmost care.

The wide pieces of the centre are generally put into the stretching strain leaving the short piece free, and thereby stretching the whole piece on an equal strain; or, to explain it more fully, if you wish to stretch a 24 in. centre piece of leather, you place your clamps eight inches on each side and leave the centre eight inches clear; this will draw up enough under the strain of the side pieces to be perfectly even, or rather, the side pieces which contain more stretch, will draw its tension even with the centre.

I also prepared a dressing or extra coating for the leather which made it very pliable and also very smooth by filling its pores. Another important improvement for dynamo belts, was making them light double, and perfectly even in weight, so that every square inch of the whole belt was of even weight and tension throughout. This caused the belt to run without vibrating like ordinary belts; to run more steady and give a uniformity of power,

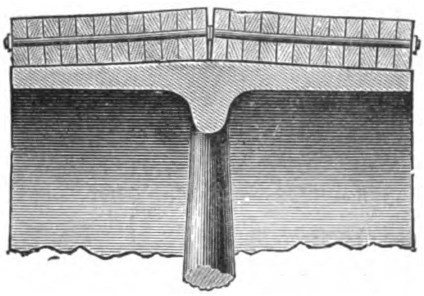

FIG. 5.—New Style with Two Bolts.

so necessary for producing electric light. Nor did the belt contain copper rivets and burs or other obstructions, but simply small wire endless screws; and its tensile strength was greatly increased by fastening the edges of the belt with these wire screws which held the leather firmly together, and yet offered no obstruction to the smooth surface of the belt.

However, no belt has ever created such a sensation in the trade as leather link belting.

This is a comparatively new article in this country, having been introduced two years ago. Since that time so many improvements have been made in this line of belting, that it can now be used on any kind of machinery. During the past two years these

FIG. 6.—Half Crossed Belt.

belts have done excellent work. They are made in the following manner: Small pieces of solid selected leather are dressed with tallow and neat's foot oil, which act as a lubricator to the joints of the pins. The leather is then put through rollers and made very solid; it is then cut into small links; this process makes a link of remarkable tenacity and strength, and one which will bear more strain than a piece of hard rolled *sole leather*. The links are then carefully assorted as to thickness and the belt built up to the required width. It is of great importance that each belt be made up of accurately assorted links, in order that an even width and perfect running belt may be secured.

A joint is of great improvement in this line of belting. Two bolts are used to each width of belt, and the two widths ingeniously joined together, forming an unbroken surface. This makes a belt which will conform itself to any pulley, whether flat, rounded, or cone.

They should be run as loosely as possible, and should not be taken up unless they actually slip. An inexperienced person upon seeing one of these link belts running on a dynamo would naturally think that the belt was loose and needed tightening, but these belts have such a remarkable grip power, that though when running the upper part of the belt is so loose that it almost describes a semi-circle, the under side is as tight as possible. Leather link belts will in time find great favor with belt makers, as they are more pliable than any flat double belt can possibly be made; and for belts running at right angles I claim that they are the only reliable belts for such a position that will give satisfaction.

ABSTRACTS AND EXTRACTS.

THE SLATTERY INDUCTION SYSTEM.[1]

FOR many years past a number of the brightest electricians of the world have been engaged in a close study of the laws governing the actions of alternating currents, and especially have directed their efforts towards solving the problems underlying the operations of induction coils or converters, used as one of the prime factors in a system of electrical distribution.

M. M. M. Slattery, one of the earliest practical workers in this latter direction on this side of the Atlantic, who has lately joined issues with the Fort Wayne Jenney Electric Light Co., has devoted much time during the past three years in working out and putting in practice a system of electric lighting in which inductoriums are used, and which, from all accounts, appears to leave little to be desired in the perfection of detail and in the success in general which has attended his practical efforts in this extensive field.

Mr. Slattery's first experiments were in the line of Gaulard & Gibbs' work, with a view to increasing the efficiency of the converter used in this system and reducing it to a commercial basis. At an early stage, however, when working in this direction, he became convinced that, owing to fundamental electrical difficulties which existed in this system, and which appeared to him impossible to eradicate—reference is had especially to the development of counter E. M. F. with the coils placed in series in the line —he turned his attention to the utilization, instead of the suppression of certain laws which govern the action of inductoriums. His next step was, instead of placing the inductoriums in series in the main line, as in the case of Gaulard & Gibbs' system, to dispose of them in multiple arc, and from that period up to the present time he has been, as stated, engaged in perfecting the multiple arc inductorium system. In working out this system, Mr. Slattery has been ably assisted by Robb MacKie, who is assistant electrician of the Fort Wayne Jenney Electric Light Co. The various factors comprising the system are shown in the accompanying drawings.

The principal features of the alternating systems of electric lighting are so well understood that it might be considered superfluous to give any detailed description thereof at this time. In a few words, however, it may be stated that the first plant put in practical operation by Mr. Slattery, in Woburn, Mass., had a primary main line pressure of 1,000 volts at the poles of the primary coil and 50 volts at the poles of the secondary coil of the converter. These converters were placed in multiple arc in the circuit, and are to-day working as perfectly as upon the first day they were set up—more than two years ago.

Dynamos.—In deciding upon the particular type of dynamos most suitable for the work to be done, two were chosen, built, and put into practical operation. These types were the Siemens' disc armature and the Lontin, and after careful and exhaustive test, the Lontin type was selected, and with many improvements, electrical and mechanical, is accomplishing remarkable results wherever it has been put to work.

It will be seen from the engraving, figure 1, that so far as symmetrical mechanical construction is concerned, in which is combined rigidity and simplicity throughout, the builders are warranted in the confidence they justly feel in the successful performance of the work that has to be accomplished by it.

When it is said that upon the armature of the machine capable of supplying 1,800 16 c. p. 50 volt lamps there are but 35 pounds of copper wire, it will be understood by those familiar with the business that the ideal construction is closely approached, and that the greatest care has been exercised in electrically disposing of every part of the dynamo, with a view of obtaining maximum efficiency from the minimum of mass. After careful experiment, it was further decided that it was more simple, more easy, and safer to operate a separately excited dynamo than a self-exciting dynamo. Both kinds were built, and the results which have fol-

1. From the *Western Electrician*, February 18, 1888.

lowed the adoption of the separate excitation would seem to indicate a judicious selection.

Figure 2 illustrates the type of exciter employed with this system, and, as will again be seen, simplicity of parts characterizes the mechanical skill which has been employed in its construction.

Converters.—**An exterior view of the converter is shown in figure 8. The interior construction is briefly described: The copper wire is wound upon a core consisting of insulated iron plates, rectangular in form, divided centrally, and placed back to back, previously having had a sufficient portion of the centre cut out, in which space the coil referred to is wound. The magnetic circuit is then closed around the sides of this coil by the other half of the rectangular plate referred to. The coefficient of induction in this converter is equal to a volt per five inches of wire, the ratio of**

danger whatever, to make and leave everything secure about the connections of the apparatus.

Instruments.—**The central station instruments, viz., pressure indicator and ammeter, are especially constructed for measurements of alternating currents and potentials, and are both simple in construction and extremely delicate in operation. A description of one instrument will answer for both. Two flat metallic spools divided at one side, have wound thereon the requisite number of convolutions of wire. These spools are mounted upon a rectangular frame common to both, one being placed in eccentric relation to the other, in order to modify the parallel plane of the convolutions of the respective coils, for the purpose of reducing self-induction. In order to obtain a due and proportional measurement of current or potential in relation to the spools a circum-**

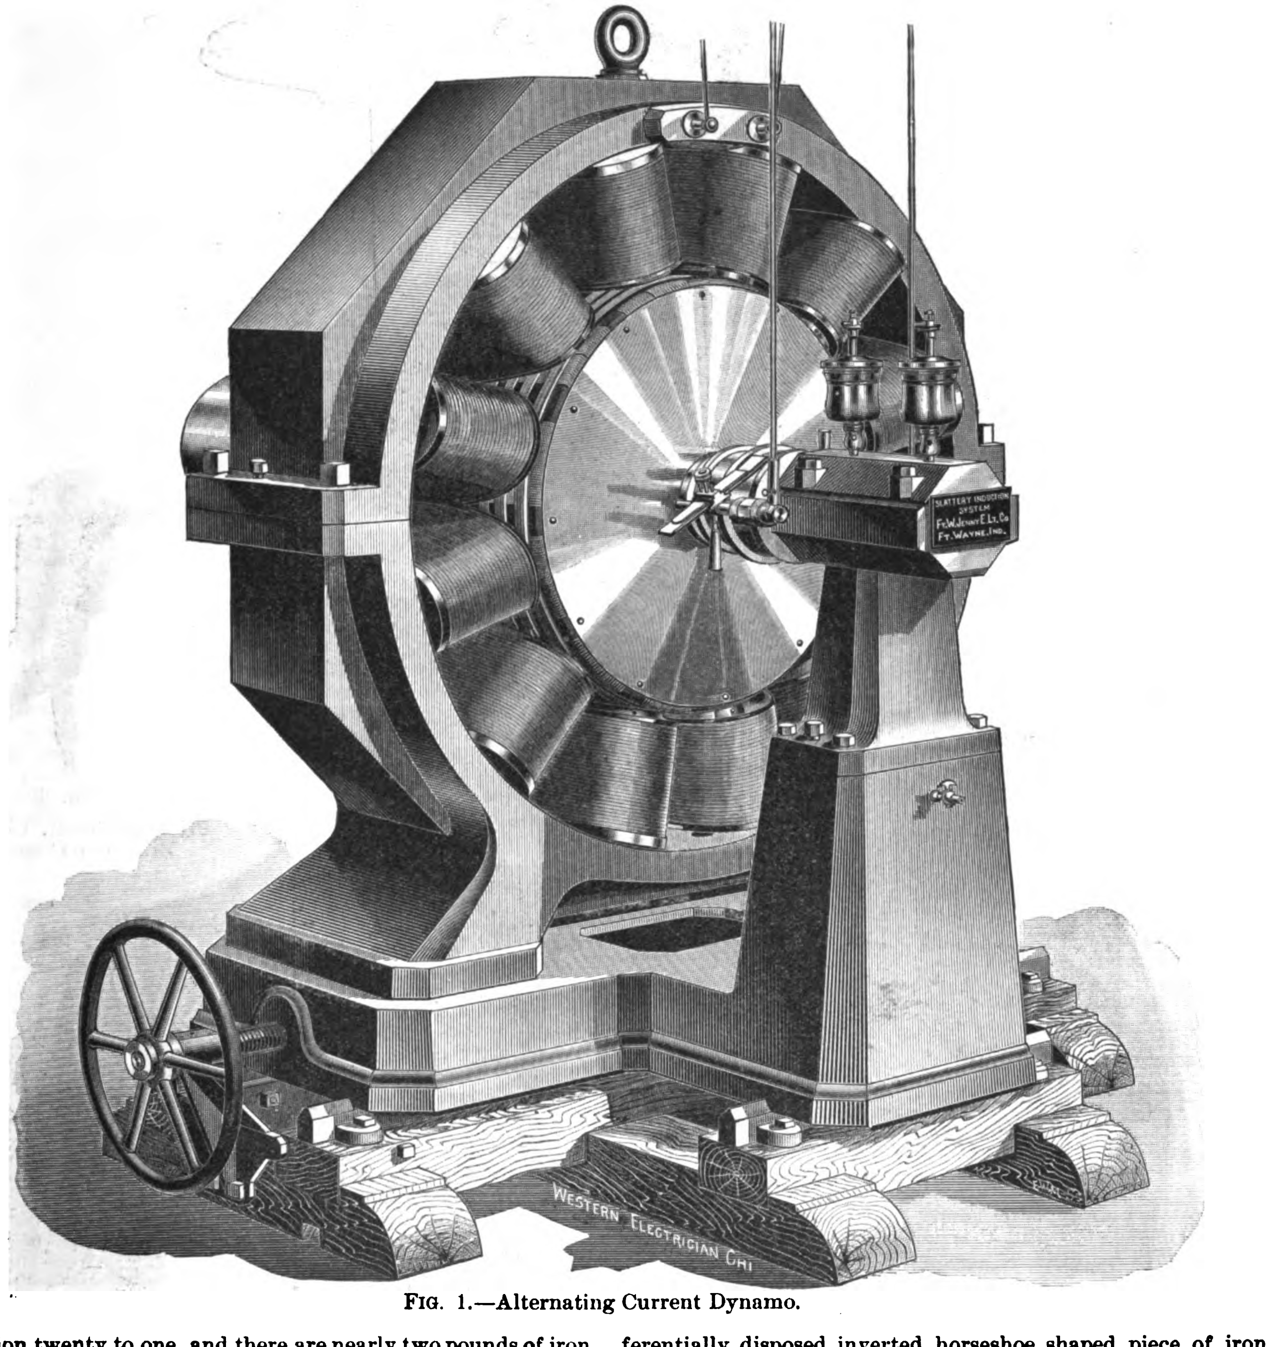

FIG. 1.—Alternating Current Dynamo.

conversion twenty to one, and there are nearly two pounds of iron per secondary ampere capacity. The working pressure of the system is 1,000 volts at the poles of the primary coil and 50 volts at the poles of the secondary coil.

A special insulating compound is used in these converters, and this is of such a character, that the chance of cross circuiting of the convolutions of the primary coils are very remote indeed. In each converter, conveniently placed, are primary and secondary fuses, which are easy of access, and exceedingly safe in event of a necessity arising for the renewal of a fuse upon the line circuit; a simple device in connection with the primary fuse enables the attendant to cut the converter entirely out of circuit during the introduction of a new fuse, thereby enabling him, without any

ferentially disposed inverted horseshoe shaped piece of iron is attached to a central shaft, which is mounted upon jeweled centres, and carries a pointer, which is deflected according to the varying potentials and strength of current.

The instruments are placed in a case having a glass front, and are disposed in a conspicuous position in the central station, so that the attendants may see at any moment what is taking place in the external circuit.

Meter.—Not the least of the important factors in this system is a meter for measuring the energy supplied to each customer, the extreme delicacy and accuracy of the working of which, can not be too highly estimated.

Multiple arc coupling device.—A very simple central station

device is used for safely and easily coupling alternating current dynamos in multiple arc. To accomplish this object there have hitherto been used electro-magnetic devices, synchronizers, etc.,

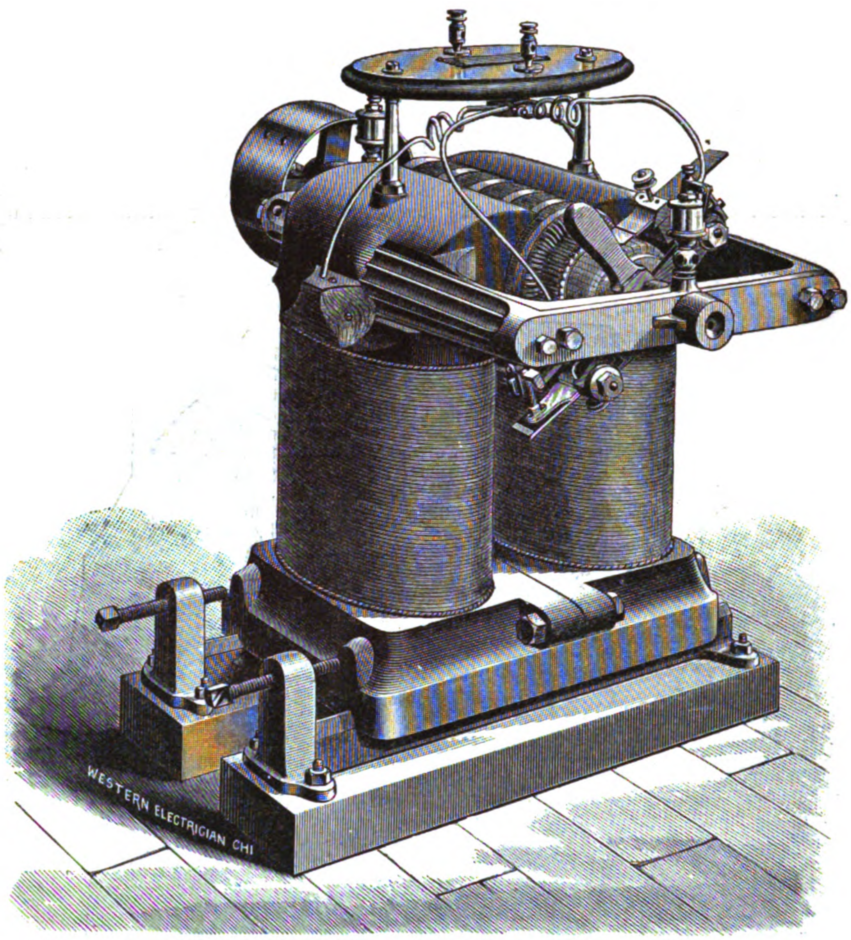

FIG. 2.—Exciter.

but as these devices require very rapid action and necessitate exceedingly great care in operation, they can not always be de-

FIG. 3.—Resistance Box for Exciter.

pended upon to perform successfully the work required of them. In the case of the apparatus that Mr. Slattery uses for this pur-

FIG. 4.—Primary Circuit. Branch Clamp.

pose, the coupling of dynamos in multiple arc is reduced to a basis of such simplicity that an ordinary central station assistant will have no difficulty in coupling and running the dynamos together.

Recorder.—Another useful central station apparatus, devised

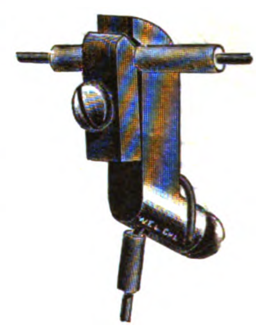

FIG. 6.

Primary Circuit. Clamp for Branch to Converter.

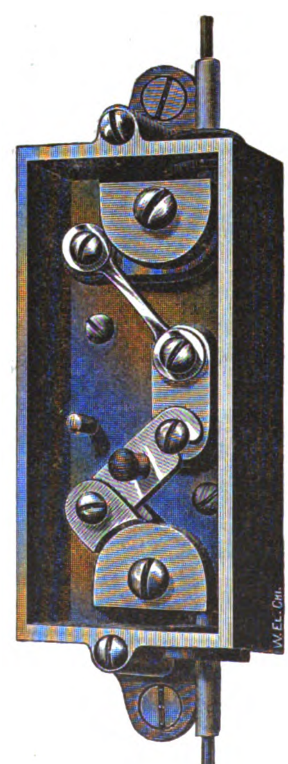

FIG. 5.

Primary Circuit. Branch Fuse Box (cover removed).

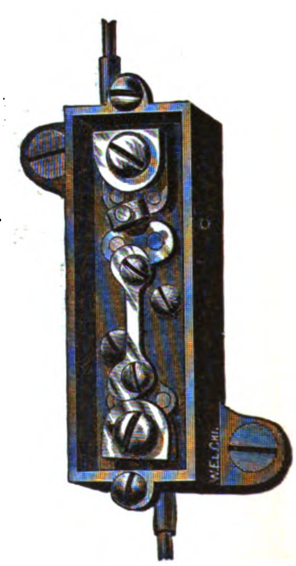

FIG. 7.

Primary Circuit. Fuse Box for Branch to Converter (cover removed).

by Mr. Slattery, is chiefly to be used by central station superintendents. This device is placed by the superintendent in proper

relation in the circuit for the work it has to do—at night, for instance, as he leaves the station. In the morning when he returns he consults the apparatus, and sees exactly the extent of the irregularity due to the carelessness of the attendant, and the electrical disturbance which may have taken place during his absence. This will, no doubt, commend itself to central station superintendents as a means of compelling, if possible, more care-

FIG. 8.—Converter.

ful performance of duty, a laxity of which has frequently resulted in many irregularities unpleasant to relate.

Arc lamps.—This system would not be complete without an arc lamp and motor. Mr. Slattery makes a special converter for operating arc lamps in multiple arc, which, although it has not yet been placed on the market, has been for some time working successfully at the factory, and preparations are now being made to manufacture these lamps and introduce them for public use.

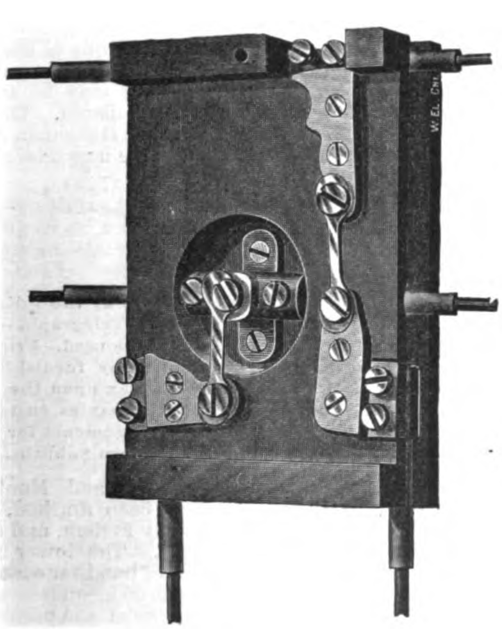

FIG. 9.—Secondary Circuit. Entering Fuse Box (cover removed).

An excellent feature about this apparatus is that arc lamps of various illuminating capacities can all be used in one general system, these capacities varying between 300 and 2,000 c. p. The converter constructed to work in connection with this lamp is only a trifle larger than an ordinary exterior arc lamp cut out, and in consequence of such desirable compactness, may be disposed of with as much ease.

Motor.—The motor referred to is still in an experimental

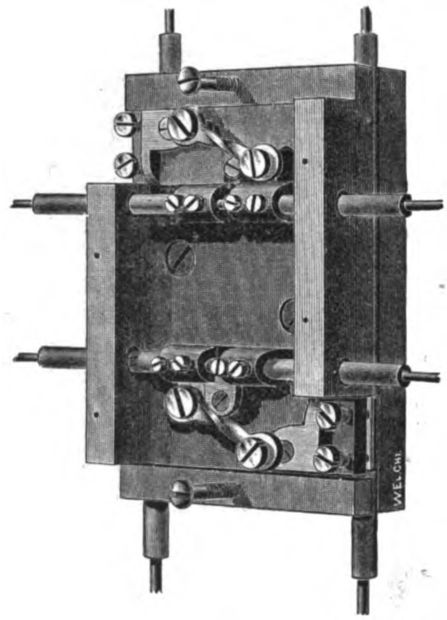

FIG. 10.—Secondary Circuit. Double Pole Fuse for Cleat Wiring (cover removed).

stage, but in an advanced one, and considering the activity and ingenuity displayed by Mr. Slattery, and his able assistant, Mr. MacKie in working out this system, it may be fairly anticipated

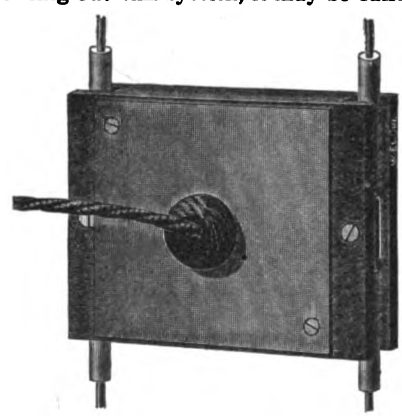

FIG. 11.—Secondary Circuit. Single Light Fuse for Cleat Wiring.

that before long the success which has characterized their efforts in other directions, will be fully realized in this.

Wiring fixtures.—Figure 4 is an adjustable clamp branch connector, used to connect branches with the main line and enables

FIG. 12.—Wall Switch. FIG. 13.—Wall Socket.

Secondary Circuit.

the lineman to dispense with the use of solder, rendering the work more expeditious, and making a far more effectual joint. In conjunction with this branch connector, is used a branch switch safety fuse, figure 5, which is placed at the junction of a primary branch and the main line. Here again the safety of

those whose duty it is to replace burnt-out fuses is considered, as they can by means of the switch, shown in the interior of the

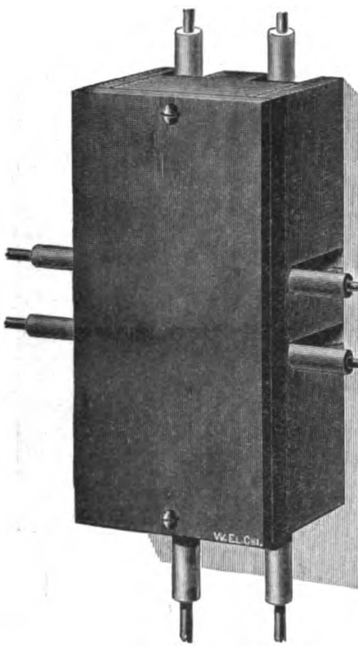

FIG. 14.—Secondary Circuit. Double Pole Fuse for Molding Wiring.

fuse box, disconnect the fuse terminal from the line and then

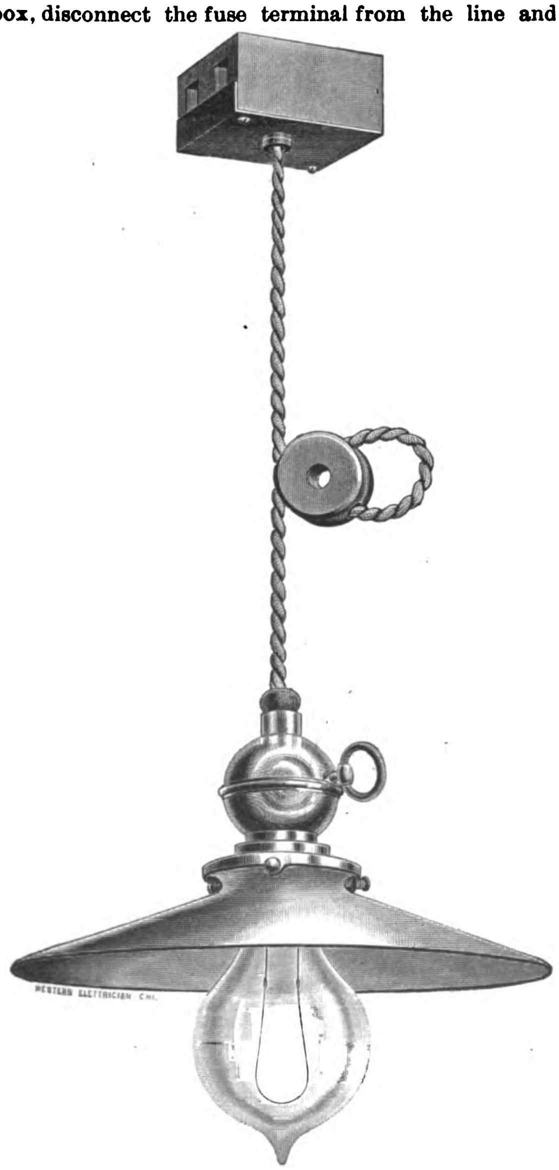

FIG. 15.—Single Light Fuse and Lamp Fixture, complete.

safely adjust the fuse. One of these boxes is placed on each side of a parallel circuit. Figures 6 and 7 are smaller sizes of figures 4 and 5, and are employed to connect the primary coil of converter with the external primary circuit. This method of introducing so many fusible devices throughout the system might be considered by some as superfluous, but if there is an error in question at all it will be considered as being on the side of safety.

Figures 9 to 15 represent the fusible wiring details, the special object in the construction of which has been greater facility in wiring and safety when wired, and evidences thorough familiarity with both plain cleat and molding wiring, and every requirement which may arise in this branch of work.

Figure 15 represents the lamp, shade-holder and key-socket. The lamps have a working life of some 800 hours, and twelve 16 c. p. 50 volt lamps may be operated with the expenditure of one horse-power of energy—results that are decidedly creditable.

NEW YORK AND VICINITY.

Explosion of Illuminating Gas in a Conduit.—The Telephone Service.—The Copper Market.—Electric Traction on Fourth Avenue

THE dangers arising from the accumulation of illuminating gas in subway man-holes are being rapidly confirmed as these structures become more plentiful. It was but five weeks ago that Leonard Jones lost his life in this city from the above cause, and on February 24, a series of explosions occurred in the unfinished subway of the Bell Telephone Co. at Buffalo, by which Fred Zott, and William Wood, employés of the Western Electric Co., were terribly burned, and another man stunned. Five man-hole covers were thrown in the air, but the damage does not appear to have been as serious as in similar explosions at Philadelphia.

General manager Eckert, of the Metropolitan Telephone and Telegraph Co., gives the New York subscribers credit for being fairly expert in the use of the telephone. Owing to the vast number of wires of all kinds used in this city, the telephone service is not what it should be, but with the early adoption of metallic circuits a great improvement is expected.

The proceedings of the copper trust are of vital interest to the various electrical industries, and a hope has existed that the advance in prices was but temporary. The information which is now public regarding the manipulation of the world's supply indicates that there is little hope for lower prices as the syndicate has contracted for the output of all important mines for three years in advance. Nothing but a decided decrease in the demand is likely to thwart the plans which have been very carefully made. While copper has been introduced for line construction by telegraph and telephone companies to a limited extent, its superiority for their use is not sufficiently marked to prevent their return to iron.

The indications for the general adoption of electric traction on the Fourth avenue railroad in this city are very favorable. The car fitted up by the Julien Electric Traction Co. is now making regular trips, and is being skilfully handled by one of the regular horse drivers assigned to that duty. Eighteen more cars are to be fitted up with such improvements in detail as may be suggested by the experience which is being daily accumulated. The horses do not take kindly to the innovation, and the stablemen and hay dealers do not look with entire favor upon the new motor car, but "it gets there all the same."

NEW YORK, Feb. 27, 1888.

PHILADELPHIA.

The Lighting of the New Grand Opera House by the Edison Co.—Mr. Powderly's Efforts to Secure a Postal Telegraph.—Another Electric Railway.—The Wharton Motor to be used.—Front Street Store-keepers think they can Economize by furnishing their own Electric Light.—The Pole and Wire Tax upon the Western Union and Mutual Union Telegraph Companies sustained by the State Supreme Court.—Temporary arrangements for the City Lighting.—Rapid Transit to the Northwestern Suburbs.

THE new Grand Opera House, at Broad and Montgomery avenue, in this city, which has recently been finished, is completely lighted by the Edison electric light system, and contains about one thousand incandescent lights. The lower foyer is separated from the auditorium by screens of handsome lead lights, studded with glass jewels and lighted with 36 incandescent lamps in various colored globes. Around the edge of the parquet there are 17 three-light burners, and in the gallery are 17 five-light chandeliers. In the foyer of the upper gallery there are 18 chandeliers of two lamps each, 120 lamps are in the ceiling, on the stage are five border lights of 50 burners each; there are also 50 bunch lights, and besides all these are electric lights in all the twelve large dressing rooms and in the green room. This immense system of lighting is completely controlled by nine levers on the stage, each lever controlling a certain section of the lamps, so that any section can be turned off without interfering with

any other. The foot-lights are of 50 burners. When lighted the opera house presents a very beautiful appearance.

General Master-Workman Powderly's recommendation that persons interested in the establishment of a government telegraph system, should petition Congress to pass an act to provide for such an institution, is being readily responded to from all sections of the United States. These petitions are forwarded to general headquarters of the order, at No. 814 North Broad street, and a room devoted to their reception is literally flooded with letters.

These petitions, which are addressed to Congress, state that the signers are citizens of a certain Congressional district, and that they pray for the framing and adoption of a statute providing for a government postal telegraph, with the reasons attached. Some of these petitions are of wonderful size. The Third district of California has forwarded a petition containing over 2,600 names. One from the Fifth, Kansas, has over 1,300 subscribers; the State of Colorado forwards one with 1,800 signers, and the Third, Massachusetts, has sent a petition signed by over 1,200 voters.

General secretary Litchman, in discussing the object of the movement, said: "We are much pleased that the signers of these petitions are not confined to the order, but represent the business element of the communities from which they come."

When the Lehigh avenue railway is put in operation, electricity will be the motive power employed. The company has completed its tracks from Fairmount Park to Second street, with the exception of about a quarter of a mile of double track in the vicinity of its intersection with the connecting railroad near Seventeenth street. It is the intention to avoid all grade crossings, and the line will not be finished at this point until it is determined to place the grade over or under the present railroad crossing. The Wharton motor, which has been tried with such signal success on the Chestnut and Walnut streets line, is being perfected for service on the Lehigh avenue road. The motor company has built 1,000 feet of track at its works, and tests are being carried on there. After the recent heavy snow storm the motor not only made its way against the accumulation of snow, but effectually cleared the rails.

The storekeepers on the west side of Front street, between Susquehanna avenue and Dauphin, the majority of whom have their stores illuminated with the electric light, have been discussing, for some time, the advisability of manufacturing electricity for their own use. They claim that the price charged for one electric light (60 cents per night) is entirely too much, and have figured it out that they can manufacture it themselves at one-third the price charged now. Accordingly a meeting has been held to perfect an organization. It is proposed that each storekeeper be assessed $150 to purchase a building and the necessary plant.

The Supreme Court has affirmed the judgment of Common Pleas Court, No. 2, in the suits of the city against the Western Union and Mutual Union Telegraph companies to recover the annual license fee of $1 for each one of their poles erected upon the public streets, and $2.50 for every mile of suspended wire. These license fees were imposed by an ordinance of January 6, 1881, but have never been collected. In affirming the judgment that court simply holds that the city, in the exercise of its police powers, has an undoubted right to impose a license fee on poles and wires, and that there is nothing unreasonable about the amount fixed for the fee.

Last month director Wagner postponed awarding contracts to electric light companies for furnishing lights on the different highways, owing to the Keystone Electric Light Company agreeing to furnish the lights at a considerably less amount per light, providing they were granted certain concessions by councils. He subsequently entered into an agreement with the various companies to furnish the lights during the first three months of the year, so as to give him an opportunity to communicate with councils and effect some arrangement by which the city would be benefited. At a meeting of the electrical committee, the director's communication asking for an appropriation to pay for this service was considered. A representative of the Keystone company was present, and stated, in answer to an inquiry, that his company was prepared to furnish lights of 2,000 c. p.

"How about the city of Philadelphia being compelled to pay more for electric lighting than is charged for similar service elsewhere?" asked one of the members.

"There are several reasons for this," said Mr. Graham. "The first thing is the number of hours each night the light is furnished, and the character of the light."

"If a contract is made for 2,000 c. p. light, why, we would have 2,000 c. p.," said director Wagner.

"Do you think that you can do better by waiting until April 1st, in awarding your contracts?" asked Mr. Graham.

"No, I don't. I can for the current year."

"It's pretty near time we had some good light at nights," said Mr. Van Dusen; "the gas is getting worse and worse."

After some further discussion the matter was referred to a sub-committee to examine into the whole subject, and report at the next meeting of the general committee.

The Rapid Transit Electric Railroad Company, which was incorporated at Harrisburg a few days ago, intends to introduce in this city a system of electric railways for the transportation of the public from the centre of the city to the extreme northwestern portion. In addition to the ordinary cars, seating twenty persons, this line will run during the morning and evening hours double-length cars, with seating capacity for fifty, thereby meeting the extra travel at those periods of the day.

PHILADELPHIA, February 16, 1888.

BOSTON.

The United States Supreme Court Inconsiderately Disappoints Speculators in Telephone Stocks.—Erie Telephone Co.'s Report.—Long-Distance Telephoning.—Death of Edward Farrar.—The Wilson Police Signals.—Extra Provision of Fire-Alarm Boxes.—The Mexican Telephone Patent Decision.—Fires from Electric Wires.—Underground Wire Franchises Sought.—Storm Signals Likely to be Suspended at Several Stations Through Want of Funds.

NOTWITHSTANDING all the cock-sure information given out by stock brokers who have private wires, and well-informed newspapers who have "inside information," the great decision on the appealed telephone cases has not at the present writing been rendered. Unfortunates, who relied on the private advices, and who carried Bell stock on margins have become tired out, as also have those would-be bears who have sold the same stock short. It is amazing that the Supreme Court has not attended to all this buzzing, fomenting and ebullition of the speculative parties who have been so anxious for a decision; they are worse than the railroad magnate who was said to have remarked, that the public might be short on future bliss, or words to that effect.

However, the Bell company do not seem to be embarrassed in consequence of the delay, it is understood that they used to sit up nights, in the early days of decisions, and walk the floor, but now they permit the other fellows to do that. In the Philadelphia case before Judge McKennon, there was a stay, because the judge wished the Drawbaugh case to be decided first by Judge Wallace, before whom it was pending, before *he* decided the case at his bar; when the news of the stay arrived at the Bell office, one of the shorthand young men, who was operating his type writer said, "Shall I stop where I am?" supposing the bottom had dropped out; as indeed many of the employers who were dabbling in the stock did, when the stock tumbled about 50 points and left them hung up. However, that did not stop them from doing the same thing afterwards, when their courage had returned.

The Erie Telephone and Telegraph Company makes the following very satisfactory report of operations for the third quarter and first nine months of its current fiscal year:

QUARTER ENDED DEC. 31.

	1887.	1886.	Increase.
Gross earnings	$160,071	$137,409	$22,662
Gross expenses	103,774	93,296	10,478

* Decrease.

The members of the Boston Electric Club, on the 31st ult., visited the rooms of the American Telephone and Telegraph Company, No. 53 Devonshire street, and tested the new telephone lines to Philadelphia, Albany and New York. In the last-named city, the New York Electric Club was engaged in opening its new club house at No. 17 East Twenty-second street, and a connection having been made, the members of the two organizations chatted pleasantly for more than two hours. The test was satisfactory.

Long-distance telephoning is now an accomplished fact for Boston. Several of our enterprising brokers and business men have leased private wires. The next thing is to build a line from New York to Chicago.

The following is from the Boston *Advertiser* :

Hon. Edward Farrar died at Keene, N. H., the 11th inst., of pneumonia, aged 66 years. He was the second mayor of Keene. He held the office of clerk of the courts for 30 years. He was the judge of the police court for 15 years, and he was a charter member of Hugh de Payens Commandery. He actually invented the first rude telephone in this country, although owing to his extreme modesty he never pushed his claim. In religion he was a liberal Unitarian. He leaves a widow and two daughters.

The Wilson police signal system is now almost ready for use by Police Division 5, South End, and it will probably be set in operation some time this week. Then superintendent of police, Small will at once begin the work of placing the necessary boxes and wires in position in Police Divisions 9 (Roxbury) and 15 (Charlestown).

Fire-alarm boxes have recently been placed on many schoolhouses in the city, and it is believed that no other city is so well protected in this respect. Special boxes have been established in many of the schools and hotels.

A City of Mexico despatch says that the favorable decision in the case of the Mexican Telephone Company is a decided victory for the Bell and Blake patents over German imitations, which are exact copies in the minutest detail of the American invention. The decision given by the First District Court will be appealed from, and recourse had to the Supreme Court. Under this decision, all instruments imitating American instruments must be given over to the Mexican Telephone Company, and every dollar of profit accounted for and turned over. The Bell and Blake patents were originally taken out in Mexico by Arthur P. Cushing, now Mexican consul at Boston, acting as agent for the American patentee.

In consequence of the above, the Mexican telephone stock has been quite active, better prices being obtained. A dividend is greatly longed for by the weary stockholders.

Ten fires were set simultaneously in this city on the morning of the 26th ult., by an electric light wire coming in contact with telephone and fire signal wires, says the *Herald*. Seven telephone boxes were burned out, and the fire alarms in the office of the Boston Board of Fire Underwriters, L. Burge, Hayes & Co., Mason Building, Kilby street, and at the central station of the Watkins fire-alarm signal. Fortunately, in every instance, the incipient blazes were discovered before they had done any damage.

An interesting record is kept by the New England Telephone Company of the number of telephones, call bells, etc., burned out by electric light and power wires, showing the efficiency of the protectors in use.

The aldermanic committee on electric wires met again on the afternoon of the 26th ult., for the purpose of further considering the petition of Messrs. R. M. Pulsifer, and others, that they may be granted a 20 years' franchise for the occupancy of certain specified streets in the laying of conduits for electric wires. Mr. Seth L. Powers, counsel for the petitioners, presented an amended petition. It provides that the franchise be given to the petitioners, their heirs and assigns, so that there might some day be a corporation formed; that only the best improved system shall be used, occupying not more than four square feet of space in a street roadway, although less may be necessary; to use only such locations as are determined by the superintendent of streets, and to pay $4 a day to such inspector as the superintendent may appoint while the work is going on; to restore streets to former condition and keep them in order for six months without expense to the city; to give a satisfactory indemnity bond of $20,000 before opening a street; to accommodate all the present and future city wires for 20 years free of charge. This petition differs from others which have been opposed in the courts in that it is for a definite period and for a consideration. But, even if the courts should decide adversely, the petitioners would lose their rights, while the city will lose nothing.

In answer to questions, Mr. Powers said the cost of maintenance of overhead wires was from $7 to $12 per mile; of conduits, much less, and better service was rendered. There are six systems of conduits in use, and we propose to adopt the best when we know what it is. In 1881 a permit was granted to have conduits laid, but nothing has since been done; therefore, this is the first organized effort of Boston capitalists to enter the business. A further hearing was given on the petition of Henry E. Cobb, and others, for the exclusive right for twenty years to build conduits in certain streets for telegraph, telephone and electric light wires. The petitioners agreed to give a bond for every street opened; to put and keep the streets opened in repair for a term of six months; to use only such locations as are determined by the superintendent of streets, and to use the best system of conduits.

Objections to granting an exclusive franchise were made by Messrs. Spaulding and Olmstead, representing a solid conduit system, and by Messrs. Burnham and Fitzgerald, representing the Franklin electric light system.

After a statement by Mr. Powers, that the petitioners would be glad if the board of aldermen could investigate all the plans and recommend the best one to the petitioners, thereby taking a great deal of work off their hands, the hearing was declared closed.

The committee on electric wires of the city government, gave a hearing on the afternoon of the 2d inst., to the remonstrants against granting the petition of R. M. Pulsifer, and others, for leave to lay conduits for electric wires in certain streets of the city. President Sherwin, of the New England Telephone Company, objected, because the petition was not sufficiently definite. Further remarks were made by Professor Cross, of the Institute of Technology, and Mr. Frederick Cartwright, of New York, and the case was then closed.

The remonstrants against overhead wires, having had the satisfaction of seeing the same placed underground to a large extent in the business streets, are now grumbling because their horses are frightened at the bonfires built over the man-holes of the conduits—to melt the ice and frost therefrom, in order that the interiors thereof may be accessible.

The sea captains and sailors hereabouts are much alarmed at the order from the War Department, at Washington, to the officers in charge of the signal service stations of the Atlantic seaboard, announcing that, the appropriation having run short, there is no money with which to pay the signal men of the several stations, and that those stations will have to be discontinued from January 20 to July 1. Captain Hayden, of pilot boat No. 3, Captain Fowler, the oldest pilot in the local service, the officers of the T Wharf Towboat Company, and others, are reported as saying that the storm signals are greatly needed at this time of the year on this coast, and if they are discontinued incalculable harm to life and property will result. The cautionary storm signals are eagerly watched for by sailors, who, when a storm is predicted, always remain in the harbor.

Sergeant J. W. Smith, who has charge of the signal service at Boston—the Boston "district" including ten minor stations—says that the display of signals will be discontinued at Chatham, Highland Light, Hull, Hyannis, Portsmouth (N.H.), and Provincetown, until Congress provides the means for their renewal. They will be continued at Marblehead, Gloucester, New Bedford and Newburyport—the more important stations in the district.

Sergeant Smith has notified the men at the posts at which the signals are officially discontinued, that the government will telegraph the bulletins if the men will display them (or the signals), without cost to the government. The men are usually telegraph operators, railway employés, or postmasters, and are paid for each time the signal is displayed—when the government has any money.

BOSTON, Mass., Feb. 16, 1888.

CHICAGO.

The Cushman and the Interstate Telephone Companies Seeking Franchises.—The Sun Electric Light Co. and the Chicago Arc-Light and Power Co.—The Death of Genl. J. L. Thompson.—The Semi-Annual Convention of the Edison Electric Light Association.—Mr. D. H. Louderback appointed General Manager of the Chicago Edison Company.—Mr. E. T. Baker Accepts a Position with the Western Electric Co.—Starting of the Thomson-Houston Plant in the Union Depot.—The Competition for the Topeka Arc Light Plant.—Statistics of Work in Telephone Exchanges.—A Clever Device for Registering Telephone Connections.—Rumored Removal of the Van Depoele Factory to Connecticut.—The Chicago Electric Club.—Western State Legislatures Anxiously Watched by Telephone Companies.—Decadence of Interest in Natural Gas.

THE American Cushman Telephone Co. has applied to the city council for a franchise to build and operate a telephone exchange in Chicago. It offers to guarantee the city and all users of the Cushman telephone against loss on account of suits for infringements of patents, and agrees to furnish telephones for eighty dollars per year. The Interstate Telephone Co. has also applied for a franchise and offers similar guarantees, with an agreement to furnish telephone service at no more than $60 per annum. The council committee to which the matter was referred, reported in favor of granting franchises to both the Interstate and the Cushman companies. The security with which the Cushman company carries on business is a good deal of a puzzle in view of the promptness with which other infringers are met with injunctions. It can hardly be, telephone men think, that the American Bell Telephone Co. fear to have Dr. Cushman's claims investigated. In many respects these claims are the most improbable which have been put forward in opposition to Bell. Whatever may be the reason why this company proceeds with its business comparatively without molestation, it seems to thrive. It is selling private line instruments and putting in exchanges in Indiana. At South Bend, there is a Cushman telephone exchange of seventy-five subscribers.

The Sun Electric Light Co. is operating about 300 arc lights and is the only considerable opponent the Chicago Arc Light and Power Co. has now in Chicago. As the Chicago Arc Light and Power Co. owns the Chicago Sectional Underground Conduit Co., which latter company is in possession of the only general underground franchise in Chicago, the Sun company is in a measure at the mercy of its powerful rival. It has accordingly appealed to the city council for an independent franchise to lay its wires

underground in consideration of which it agrees to light the streets in its territory, or wherever its lines run, at bare cost, the cost to be estimated by the city comptroller, and to pay to the city 2½ per cent. of its gross earnings. The council committee to which this application was referred reported in favor of accepting it and granting the franchise asked for.

The large central station of the Chicago Arc Light and Power Co. is now in successful operation. There are in use two large compound condensing engines built after plans prepared by Mr. E. F. Williams, of the Williams Engine Co. The transmission of the power to the lines of shafting is accomplished by ropes. From the shafting to dynamos the ordinary leather belt is used. The station has many novel features and is an object of considerable interest to visitors to the city who are interested in electric lighting.

The death of General J. L. Thompson, on January 31st, caused profound sadness among a wide circle of his friends and associates in electrical enterprises. At his funeral services which were attended by the most prominent members of the bar and bench in Chicago, and other well-known men who were General Thompson's personal friends, there were present representatives of the Western Electric Co., the Chicago Telephone Co., the Chicago Arc Light and Power Co., the Chicago Edison Co., the Central Union Telephone Co. and the Western Union Telegraph Co., in nearly all of which companies the general was a director at the time of his sudden death.

The eighth semi-annual convention of local Edison electric light companies met at the Grand Pacific Hotel, the 8th, 9th and 10th of this month. About 50 companies were represented. Mr. Edison himself was present and the meetings were said to have been very interesting. Mr. D. H. Louderback has been appointed general manager of the Chicago Edison Co., and assumed the duties of his position on February 15th

Mr. E. T. Baker, whom telephone men will remember as connected with telephone companies at Evansville, Ind., and Nashville, Tenn., has accepted a position with the Western Electric Co.

The Thomson-Houston electric light plant in the Union depot, which consists of 60 arc lights and 800 incandescents, was successfully started the last of January and has been in continuous and satisfactory operation ever since. This is the third of the five principal depots of Chicago which is lighted by electric lights. The Dearborn station has the Western Electric system, the Lake Shore has the Jenney.

There was the usual spirited contest between electric lighting companies over the contract recently let by the city of Topeka, Kans., for a 120 arc light plant. The bids put in by the various companies ranged from $26,950 by the Thomson-Houston Co., to $23,210 by the Western Electric Co. And the guaranteed cost per annum of operating the plant from $10,800 by the Brush company to $4,300 by the Western Electric Co. The Jenney Electric Co., of Indianapolis, were declared by the city council to be the "lowest responsible bidders," and received the contract.

Some of the telephone exchanges in the larger cities in the west have been keeping records of the work done by each operator. Mr. Durant, of St. Louis, has the highest record for a short space of time. In five minutes one operator made 53 connections and disconnections. The daily total and average per operator at St. Louis, however, is surpassed by the exchanges at Omaha, Kansas City, Nashville and New Orleans. The highest record for an hour comes from Nashville, where one operator made 248 connections and disconnections in one hour.

Mr. W. W. Smith, of Kansas City, has devised an ingenious arrangement for keeping record, automatically, of the number of connections each operator makes. A tinsel sleeve on each cord closes circuit each time it passes through the weight pulley and moves forward a hand on a dial one point.

It is stated that a syndicate has purchased the plant and patents of the Van Depoele Electric Manufacturing Co., of this city, and that the Van Depoele factory will be removed to Birmingham, Conn.

The Chicago electric club rooms were made the headquarters of the delegates of the electric light convention who went on to Pittsburgh on the afternoon of Monday the 20th in a special car. The rooms of the club have been more than usually lively and interesting of late, owing to the acquisition of handsome billiard tables, which are very well patronized. Only one meeting of the club was held this month owing to the absence of so many of the members at Pittsburgh, on the regular date of the second meeting. Dr. Whitefield read a very interesting paper on the uses of electricity in dentistry.

The legislatures of Kentucky, Ohio, Iowa, Utah and Wyoming, are the only ones in session in the west. Their proceedings are anxiously watched by telephone men, but the impression is that pending the decision of the telephone case by the United States Supreme Court there is little likelihood of any such action on the part of the legislatures as has led to such unfortunate results, both to the telephone company and to the community in Indiana. The House of Delegates in St. Louis, however, is considering a bill introduced by delegate Mohan, which fixes the rental of telephones in that city at $50 per annum.

The natural gas excitement, which never reached a very high pitch, has about died out. The principal interest now centres in the project to pipe the natural gas from the Indiana wells. The nearest wells of sufficient capacity to supply Chicago are at Muncie, Indiana, about 150 miles away. The plan of piping the natural gas this distance is seriously discussed, although the cost of such an undertaking would be enormous. In the meantime continual prospecting is going on at points nearer Chicago, but so far without very encouraging results.

CHICAGO, Feb. 20, 1888.

ELECTRICAL NEWS AND NOTES.

THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

MEETING OF FEBRUARY 14.

The president, Mr. T. Commerford Martin, occupied the chair.

Mr. R. W. Pope, secretary, made the following announcements.

At the regular monthly meeting of council, held December 6th, 1887, Dr. F. Benedict Herzog, president of the Herzog Teleseme Co., New York, was elected one of the managers of the Institute for the unexpired term of the late Sidney F. Shelbourne.

At the regular monthly meeting of council, held February 7th, Mr. John W. Howell, electrician of the Edison Lamp Co., Harrison, N. J., was elected one of the managers, to fill the unexpired term of Mr. William Lee Church, resigned.

The following named gentlemen were elected to associate membership in the Institute:

Professor W. D. Marks, Professor of Dynamical Engineering, University of Penn.

Sir David Salomons, Baronet, Tunbridge Wells, England.

Willard E. Case, Physicist, Auburn, N. Y.

Edward H. Johnson, President, Edison Electric Light Co., N. Y.

W. H. Wiley, Treasurer American Society of Mechanical Engineers, N. Y.

M. D. Law, President Philadelphia Electrical Society; Superintendent Brush Electrical Co., Philadelphia.

Montgomery Waddell, Superintendent of Underground Construction, Edison Machine Works, Schenectady, N. Y.

Gustav Pfannkuche, Electrician Brush Electric Co., Cleveland, O.

James Jerritt, Plymouth, England.

W. F. D. Crane, Electrical Engineering Department, Cornell University, Ithaca, N. Y.

Frank R. Harding, Patent Attorney and Elec. Expert, Washington, D. C.

The twenty-fourth meeting of the Institute will be held on Tuesday, March 13th, at which a paper will be read by Lieut. F. Jarvis Patten, entitled "Some Old and New Applications of the Alternating Current."

The President—Dr. Duncan is already so well known to a great many of us personally and to all of us by reputation, as to need no introduction. I will therefore ask him to proceed at once to read his paper on Alternating Current Motors.

Dr. Duncan then read his paper. (See page 85.)

DISCUSSION.

Mr. Wolcott—Dr. Duncan's paper throws a rather different light upon the subject of alternating current motors from that derived from the paper of Mr. Stanley. From Mr. Stanley's paper we concluded that the alternating system, all the way through, was slightly more economical than the direct. But Dr. Duncan has shown, I think pretty conclusively, that there are various losses there which we do not have in the direct system. The loss from heat, which depends upon the square of the current, I think is very neatly demonstrated;—the work depending on the product of the current and the electromotive force changing in sign whenever the electromotive force changes, while the loss in heat is constantly plus because the square of the minus quantity is plus. There is one advantage, I think, in the alternating system which is entirely of a practical nature irrespective of the efficiency, and that is that you do not use any commutator at all. I know one of the greatest practical difficulties in both motors and dynamos is the trouble due to commutators. Of course in favorable conditions of working, the commutator may last a long time without need of repair; but, as I have had reason to observe especially of late, in railroad work, the commutator gets used up pretty quickly in running street railways. If there is any possibility of running a street railway with an alternating current motor, I think it would be a great advantage even if it were not so economical as direct current motors. Even if it lost twenty-five or thirty per cent of the energy more than the direct motor, I think in some cases it would be preferable.

Mr. C. O. Mailloux—I would like to remark with respect to the application of alternating current distribution to the purposes of electrical traction, brought forward by Mr. Wolcott, that it will probably be some time before we succeed in utilizing it, however great may be the advantage of its use; because the alternating current motor fails to afford one of the chief requirements

demanded in a motor for electrical traction—namely, capacity for producing great torque or effort at the periphery of the armature at the time of starting. This is exactly what the alternating current will not do. Dr. Duncan has pointed out the necessity for gradually putting the load on, so to speak ; while as we know in electrical traction, it is necessary to develop large pulling capacity or effort at once. There is a great deal of confusion in that respect as to what is really required of a motor. You may rate a motor of a certain power, and it may be capable of giving you that energy when running at a certain stated speed, yet the motor may be for all that very far from answering the purposes which it must fulfill in traction, because at the time of starting the car the effort required is more static than anything else, and while in order to measure kinetic energy by the standards which we have of foot-pounds we must have motion and pressure, or feet and pounds,—at the time of starting the car we have only pounds and not feet. In other words, it is a static, dead pull, and the motor must be capable of supplying that pull or else it cannot be expected to succeed in propelling a vehicle of any description ; and while a motor, might be capable of developing its nominal power and more than that when running at a given speed such as would propel the car at its rated miles per hour, yet it might prove quite inadequate at the time of starting, from the reason that it is not so organized as to be able to develop that effort at the periphery of the armature which is necessary to give the static pull ; and that is wherein the alternating current motor does not seem to me to give any hope, at least for the present, and for a considerable portion of the future ; because we would have to use machinery, such as friction clutches and various other devices of that kind so as to gradually apply the work to the motor.

Mr. F. B. Crocker—There are two or three practical points that suggest themselves to me. In the first place, Dr. Duncan mentions the great cost of laminated field cores, and he speaks of it as if it were practically a bar to the use of laminated fields. If I were going to make a wrought iron field—if I were bidding for a contract to make wrought iron fields, I would prefer to make them laminated rather than make them of forgins.

In respect to putting on a load suddenly, that is a difficulty no doubt, and a serious one ; but still the load does not go on with the mathematical suddenness that Dr. Duncan speaks of. The belt will squeak, there will be a smell and the load will gradually come on, and in ordinary cases where the load is great, but not very great, it will come on gradually, the motor will take it and run along with it. Of course that is a question of degree ; in some cases it would—in some cases it would not.

Mr. Mailloux pointed out the difficulty of applying alternating current motors to car traction—they have not the torque, they have not the snap to them that the continuous current motor has, so far ; and the problem is to increase their effect—make them more powerful with respect to their size. The same holds good, more or less of alternating current dynamos, I believe. They are large and clumsy for their output. But alternating current motors of the two classes that start themselves are still more clumsy and large for their weights, and those are the two classes which I look to as being the ones to improve and to get into practical shape.

Mr. Mailloux—Those alternating motors which would be able to start themselves and which Mr. Crocker thinks might be able to develop the torque required are the very ones which are no longer free from the disadvantages of devices for commutating and other troubles of that kind which are incident to the continuous current motor.

Now as to the torque production, I think that the objection still holds good, because the trouble of heating as it is related in some way to self-induction—or, at least the production of eddy currents in the mass of the iron itself, even though it be eliminated, still applies ; and as in order to produce a powerful effort at the periphery of the armature it is necessary to increase the current very largely, I doubt very much if the curve of torque would be such as you would obtain from a continuous current motor. I fear that it would not rise so quickly and that it would reach the limit very much sooner. Then, besides, I do not see how it would be possible, with the present resources of the art to regulate the current so as to render the use of the motor for that purpose as elastic as the continuous current motor, because there are a number of limitations or conditions imposed by the current itself which are very hard to overcome.

Lieutenant Patten—Dr. Duncan has shown us that the curve of counter-electromotive force has a variable position with respect to mean—oscillating from side to side—and I wish to ask for information whether any such oscillation takes place or not provided the motor is running under a constant load.

Dr. Duncan—I think the oscillation certainly would take place no matter what load is on the motor ; because in a part of every period—and a period takes up only $\frac{1}{300}$th of a second, the motor is not a motor at all, it is a dynamo. That is it is absolutely putting current into the main line. The only way to get the energy and throw that current into the main line is by decreasing its speed and drawing from its energy of rotation. Therefore, where it is in those areas it will slow down in speed. Where it is in the larger areas it will increase its speed. But the oscillation will occur whether the load is constant or not.

Lieutenant Patten—The question is fully answered with a single exception, regarding the high number of alternations. I would presume that the oscillation referred to is infinitesimal in its character and would make no difference in the practical regulation of the motor in a finite amount of time.

Dr. Duncan—If the motor were driving a load which had a considerable inertia—any revolving apparatus which had a considerable inertia compared with the amount of work, the amount of the oscillation would be infinitesimal. But if the motor were light and were lifting a heavy weight, then the amount of oscillation would be very noticeable and would seriously decrease the maximum work which the motor could do.

Mr. Crocker here made mention of recent successful experiments that he had made in regulating alternate current motors and obviating excessive sparking, but did not describe them.

Mr. S. S. Wheeler—There has been considerable discussion about the torque of an alternating current motor, and Mr. Mailloux prefers the direct current motor for car traction, because when the car is going slowly, or starting, the motor going slowly will draw a heavier current and will give a tremendous power momentarily. There are two classes of direct current motors, one of which does not increase its torque when the speed is slow, and the other does increase its torque—the constant current and the constant potential motors. The alternating motors which have been described seem to resemble the constant current motors in having a constant torque. I would like to ask Dr. Duncan to give us a little information about what can be done in shifting the proportions or changing the design of alternating current motors to make them resemble more closely the constant potential motors so that greater torque will be secured at low speeds.

Lieutenant Patten (who had previously arisen and drawn upon the blackboard the figures below)—I have designed a form and made some elementary tests of a motor of the kind suggested by Professor Thomson in his paper last spring. I have always regarded Professor Thomson's motor with a great deal of admiration. It would seem from some of the discussions we have listened to that whatever work we are going to get out of an alternating system must be a question of difference between two factors opposed

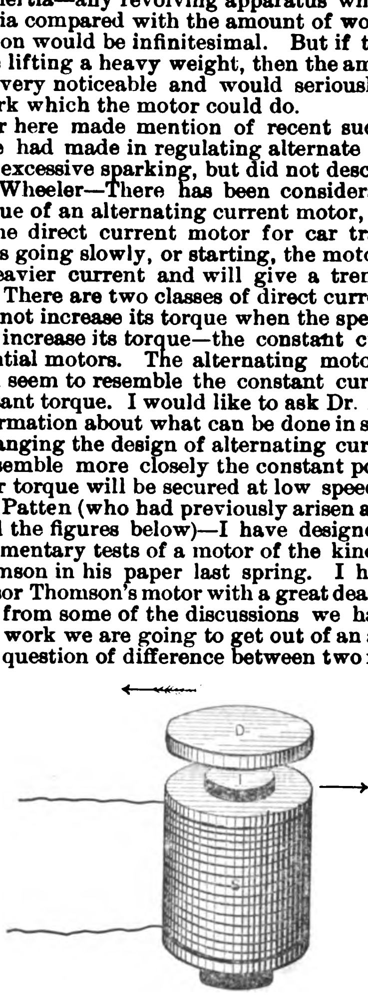

FIG. 1.

to each other—the self-induction of the circuit and the power generated as well as the heating. Inasmuch as all our results must be due to the difference between the two quantities, I have worked upon that line, trying to give that difference its greatest possible chance to do some work. If you will remember, Professor Thomson's motor, as Dr. Duncan has explained it to-night, consists in a fixed field, and a revolving armature, the circuit of which was closed when it came into position of action ; at that point the circuit is momentarily closed. But it seems that the Professor has adhered a little too closely to the ordinary form of motors. We are apt to stick to elementary ideas in applying new principles. The Professor undoubtedly elucidated a new principle, but I think it should be applied in a new way ; that is, inasmuch as the effort—the rotary torque to be used there is due to the difference in action, instead of a sudden push or pull, it should be applied so that it would have that effect. The principle you all remember. Figure 1 shows a solenoid with an iron core, and a closed circuit of high self-inductive capacity. The alternating currents are sent through the solenoid. There is an action tending to separate these two parts, either in the direction of the arrow, or the opposite, according to circumstances ; and inasmuch as this is due to electro-inductive repulsion, as described by Professor Thomson, and is due to the difference of two efforts, we can hardly expect it to be great ; and for that reason, instead of putting this force where it works at a slight advantage, in my design I propose to put it where it will work at a maximum advantage. Figure 2 will represent an end view of the machine which I designed. This is the axis of the machine, and about it are arranged two sets of four solenoids. I have numbered them from one to eight. The even numbered ones are all arranged in one plane ; the other ones in another plane, secured to the same spindle. Figure 3 is a side view of the machine. Arranged around the periphery are the closed circuits—copper discs D, D, D, D. These discs are put as far as we can carry them from the axis of rotation without increasing the size of the machine. The purpose of this is to put the action thus genera-

ted as far from the spindle as possible. There are two sets of these copper discs as shown here in side representation, and these sets of solenoids arranged on a spindle here are so connected that they come alternately into action, Just, for instance, as 1, 3, 5 and 7 are passing these four discs, the commutator throws the alternating current through that set. The other set, which then has no current comes into action in the same manner. The result is that there is a continuous torque exerted at a distance from the spindle where it can act with some advantage. The circuits of the machines are shown here. This is the connector through which the current enters the machine. These represent on each side the four coils in each of these series. Here are four coils—2, 4, 6 and 8, connected in series, and on this side the odd ones similarly connected in series. The other terminal of the machine is an ordinary eight part commutator, to which alternating parts these series are connected in alternations. The trailing brush then sweeping over this turns the alternating current into these different sets alternately. The result is we have a machine in which there is a con-

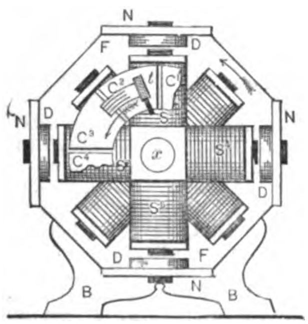

FIG. 2.

tinuous effort. I have illustrated merely the principle. These may be increased in number indefinitely and the rotary torque of such a machine would be as constant at its starting point as at any other time. I have got fairly good results from the elementary test.

Mr. R. M. Hunter informed the meeting that he had successfully met many of the difficulties that had been pointed out in alternating current motors, but gave no description of his machines.

Mr. Waring—I fail to perceive the particular advantage in running street cars or of applying alternating currents for the transmission of power. We all know that its particular advantage in incandescent lighting lies in the fact that we cannot use lamps of any higher potential than 100 volts, unless we use them in series, of course, and at the present stage of the art of electric transmission of power it is not practicable to transmit power—even continuous currents—at any higher electromotive force than probably 500, or, I should say, at a maximum, especially in street railways with central conductors or overhead conductors, of over 700

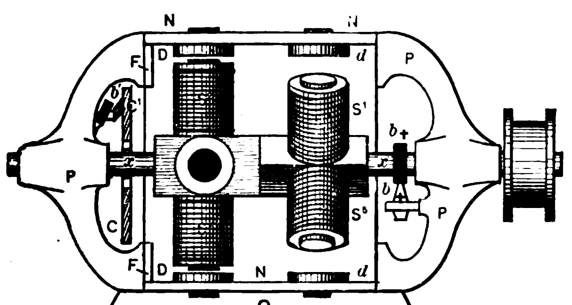

FIG. 3.

volts potential. Therefore I would like to say that I cannot see any particular advantage in using an alternating current when a continuous current will do.

Mr. Wheeler—I would like to have Dr. Duncan tell us something about the comparison of the torque of the alternating current motor with the direct constant current and the direct constant potential motors, if he is willing.

Dr. Duncan—With regard to using these alternating currents for street cars, I myself, with Mr. Waring, cannot see the advisability of using them at present, till we know a good deal more about them, while we have continuous current motors which I think are at present very much better.

With respect to the torque of the alternating motor it will be the maximum when the period of the electromotive force is the same as the period of the counter-electromotive force. For instance, if you have two curves (illustrating) that represents the curve of the main line or the curve of the dynamo which is supplying the car. Now we cannot get a greater maximum than by using a curve whose period is the same as this (illustrating) or whose phase is also very nearly the same. If we took a number of reversals that way, of course the product would be very much less. The greatest torque will be then when the reversals of the electromotive force—we call this the electromotive force—are the same as the reversals of the current; that is when the motor is at its normal speed. Of course, for street car work we want to start at a very slow speed, and there, with an ordinary type of alternating motor—I do not refer to any special types which have been brought forward and more or less described—but with an ordinary type of alternating motor the torque at first is very small indeed; and again, if we are to feed our motor from a determined source of power I do not see myself how we can make torque great at a slow speed. Of course if we make the current an alternating current then the period of our alternation of electromotive force and counter-electromotive force we can make the same, no matter what speed we use. But if we are to drive that motor from a dynamo that has a sudden and rapid number of reversals I cannot see that the torque will be great unless the dynamo has in reality reached its maximum speed. For the maximum work which can be obtained from an alternating motor, Mr. Hutchinson has kindly worked out the problem and finds that if we make the ordinary suppositions and work the motor at its maximum the expression for maximum work is a very simple one—E square divided by 8 R, where E is the maximum value of the electromotive force and R is the resistance of the machine. It is independent of the self-induction and of any other data. There are conditions which Mr. Hutchinson finds in his equations which will enable us to design a machine to give this maximum work. After we have designed it, the maximum work to be obtained is E square divided by 8 R. That is about one-fourth of the work that would be obtained from the same source by a continuous current motor.

There is another very curious thing; in order to get the maximum work from a motor which we obtain from a Siemens alternating dynamo, the counter-electromotive force is greater than the electromotive force of the dynamo. If the electromotive force of the dynamo is one thousand volts we find that the counter-electromotive force is almost fifteen hundred volts. That being the fact, the work, as I said, is E square divided by 8 R, which is about one-fourth of the work of a continuous current machine, put between the same mains made in the same way? The torque, as I said, would be greatest when the machine is running at its full number of revolutions.

Mr. Crocker speaks of a machine, when a load is suddenly thrown on, gradually bringing it up to its maximum, and the belt squeaking. If he tries the experiment he will not find the belt squeak, but it will suddenly stop; because unless that load is brought up to its full number of revolutions, in one period of reversal, in the Westinghouse system, in $\frac{1}{300}$ of a second, the motor will stop. Of course some arrangement has to be devised to stop that. He speaks of only using these motors where the maximum load will not be thrown on suddenly. Of course that is limiting the use in such a way that the motors could hardly be commercially applied.

I cannot see that an alternating motor such as I have described, that is a dynamo working backwards with a continuous current to start it and inside the field, will be at once practical. You might say that it complicates it by putting a commutator upon it. But the commutator is of the simplest kind. There is no wear of the brushes except in starting it, because after the machine is started the brushes are raised, and when it has reached its full number of revolutions you have no wear of the commutator or sparking at all. Of course that is the time we have the greatest amount of work.

Lieutenant Patten has brought forward a very interesting form of machine, a modification of Professor Thomson's plan, which we cannot but regard with the greatest admiration. The difficulty, as I can see it now, in such a machine as this is, that, as I understand it, Lieutenant Patten has revolving electro-magnets that come opposite copper pieces. Am I right?

Lieutenant Patten—That is the idea.

Dr. Duncan—The only difficulty in that is that currents will be induced in those copper pieces in order to cause the revolution of the armature. Now what becomes of the energy of those currents? Evidently it is lost in heat. If the energy of rotation of the motors is very great, the current induced in those pieces of copper is great. Therefore the loss must be great. For myself, I think that the two probable forms of motor are the motor I have described and some modification of Professor Thomson's motor. Whether Lieutenant Patten has arrived at that modification I do not know and of course cannot tell without further data and experiment.

Mr. Crocker again speaks of the sparking of the alternating motor being a minimum when it is regulated. I do not believe in alternating motors that have commutators, as they are ordinarily called—that is where they have a number of bars through which the current is constantly flowing. I have tried experiments with continuous current dynamos worked as motors and find very little effect from them. In order to get a large output

we have to have the counter-electromotive force of the motor equal to the self-induction of the motor, field magnets and armature, and that is simply impossible in practice. If you join up a series motor that has an alternating source of electromotive force, and then a continuous source of electromotive force, both five horse-power machines, in the alternating machine you can stop it by just laying your hand on it. With the continuous current machine, of course, you have an immense power there.

With regard to laminating the cores of the fields, I am very glad to hear that it is a non-expensive process. I have no doubt, if that is the case, it would have a distinct advantage in alternating dynamos of every class, because the alternations of current in the armature must cause certain induced currents in the poles, and if we can build a laminated pole more easily than we can a forged pole, I think it would be policy to make all our poles laminated. However, I have had no experience in that at all and can hardly discuss it.

Mr. Waring made some remarks which embody my sentiments with regard to using alternating current motors for street cars. I do not see the use of an alternating current motor on a street car. The power of doing work is about one-fourth the power of a continuous current motor, and the only difficulty in a continuous current motor lies in the commutator—in the brushes. There is trouble, I suppose, when the car goes both ways. Now that is a matter of detail, and with properly constructed brushes there should be very little trouble. If the commutator bars were made hard enough we would have very little wear. If they were made properly we have absolutely no sparking. I think I saw somewhere a reference by Dr. Hopkinson to a method of preventing sparking. It is well known in laboratory work. I will illustrate it briefly (making a sketch). This is our brush bridge over that coil. We have a current in the short circuited coil. The current comes up here, goes through that coil, goes through the brush out of the main circuit. This coil is short circuited. Now when that coil reaches this position the short circuited coil is suddenly thrown into the main circuit. The effect of that is to suddenly change its current, if its current in this position is not exactly the same as half the current in the main line. Now a change of current taking place in an infinitely short time, it would develop an infinitely high electromotive force. It does not take place in that time, but rectifies itself by having a small spark going across and the current being still partially short circuited. That can be obviated by having behind this brush another brush—the resistance between this brush and the circuit being four or five ohms, or something of the kind. Then the current will rectify itself by passing through that auxiliary brush, and though some energy will be lost, still not more than in the sparking and wear of the armature.

I think these are all the questions that have been asked, and I will say again that I have a firm faith in the ultimate doctrine of alternating current motors, and I think that the two forms to which we must look for results are either simply the dynamo reversed, such as I have suggested, or some modification of Professor Thomson's dynamo. (Applause.)

The President—It must be a source of great gratification to all members of the Institute to see from the records of the society how far the papers which have been brought before us during the past year have served as the basis of those very interesting and important investigations into the subject of alternating currents. The paper which we have had before us this evening is a very valuable contribution to the literature of the subject and it has afforded us all very great pleasure and profit to listen to it.

The author of the paper to be read before us at the next meeting will be Lieutenant F. Jarvis Patten.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

ANNUAL MEETING (SIXTH SEMI-ANNUAL) PITTSBURGH, PA., FEBRUARY 21-23, 1888.

THE meeting was called to order at 12 M., February 21, at the Monongahela House, the President, Mr. J. Frank Morrison, occupying the chair.

The President addressed the convention as follows :—

Gentlemen of the convention :

When the National Electric Light Association, in its wisdom decreed that its next meeting should be held in this city, it was certainly an evidence of our faith in the stability of the business in which we are engaged.

The cheapest of coal, the natural gas,—every element that nature could furnish for illuminating purposes, are here spread out freely without money and without price.

To face these existing conditions, the electric light, which is comparatively expensive must have behind it the backing of nerve and courage and an unbounded faith in the good taste of the people of Pittsburgh, who, with its greater cost have adopted it in preference to that of its mighty competitors,—that light which not only illuminates but adorns their dwellings, their mercantile houses, and their public buildings.

Seven years ago the first electric light company was started in Pittsburgh with 14 arc lights. It struggled along against the prejudice, against time-honored usages, for six years, at which time 300 lights were burning where there had been but one. Here a new era opened, and within the short space of 18 months the electric lighting business increased to 350 arc, and 2,000 incandescent lights which now blaze in a constellation of glory, reflecting credit upon its progenitors. During the past six months we find that great progress has been made in cheapening the methods by which electric lighting is produced ; this is noticeably the case in the arc lighting business. The extension of arc lighting since our last meeting has been something marvelous, while even that has been outstripped by incandescent lighting, both by direct and alternating systems.

There are to-day in this country at least 3,000 isolated arc or incandescent plants, and over 1,000 central stations. At our last annual meeting there were in operation in the United States, approximately, 125,000 arc lights. Since that time there have been installed and contracted for probably 50,000, bringing the present actual total within the neighborhood of 175,000 arc lights.

The number of incandescent lights at our last meeting was slightly over a million and a quarter. The installations and contracts made since that time are reported to foot up nearly half a million, bringing the present total to about 1,750,000, giving, it will be noticed, on the whole business a proportion of about 10 incandescent to one arc. These are statistics which exhibit extraordinary growth and yet are conservatively estimated.

I beg again to urge upon the members of this association, the necessity of intelligent and well directed efforts toward the more perfect construction of lines and installation of apparatus. While some fatal accidents have marred the record of the past six months, I am glad to say that they have been fewer in number and less chargeable to the danger of the system itself than have been similar casualities in any other calling that involves the use of power-driven machinery. The attendance at this meeting is sufficient evidence of the success of this association. The secretary's report shows a membership of 168. By reference to the report of the treasurer, we find that a fairly good financial showing is made. With a debt of only $98, and with $971 in the treasury to cover all expenses of the present fiscal year, we need have no fears on that score.

Considerable progress has been made by Arthur Steuart, chairman of the legal committee toward bettering our condition in the patent office. This is a matter to which your attention will be strongly directed during the present convention, and I ask for it your calm and careful consideration. You will be called upon to decide whether or not further steps shall be taken in the direction already pursued. I am seriously of the opinion that for the better protection of those engaged in the electric lighting whose first investments depend largely upon the validity of their patents, we should, if it is possible to do so, prosecute to a successful conclusion a work so well begun by the legal committee.

Papers will be read as follows: on "The Practical Side of the Distribution of Alternating Currents from Central Stations," Mr. T. C. Smith, Pittsburgh ; on "Underground Conduits for Arc Light Wires," Mr. W. W. Leggett and Mr. Jesse M. Smith, Detroit ; on "Electric Motors," Dr. G. A. Liebig, Baltimore ; on "The Economic Value of Steam Pressure Records," Jarvis B. Edson, M. E., New York ; on "Leather Belting," its Origin and Progress, Mr. Charles A. Schieren, New York ; on "Independent Engines, in Incandescent Light Stations," Mr. W. Lee Church, Pittsburgh ; on "How Can We Protect our Watches from Magnetic Influences?" Dr. Philip Lange, Pittsburgh.

Permit me to congratulate the association upon the excellent work done by Mr. Duncan, chairman of the executive committee, who has been so ably assisted by his colleagues, and who has shown his signal executive capacity by the excellent manner in which he has prepared for the prompt transaction of the business of the association, and for the comforts of its members.

President Morrison said further :—I desire to call your attention to one or two points which reflect a great deal of credit upon the citizens of our own country, and perhaps, to put it mildly, an implication of negligence on the part of those abroad. Statistics show that in this country we have 178,000 arc lamps in service and also a large number of incandescent lights. Now the question naturally arises, why should we have made such headway on this side of the Atlantic and why should the business have been practically at a standstill on the other side. The answer may be given in two words—vicious legislation. If one absolutely inimical to progress had planned out an act of parliament which would have absolutely quenched electric lights in Great Britain and Europe he could not have better succeeded than those who framed that infamous act known as the Parliamentary Lighting Act, which has paralyzed that industry in England, has smothered invention in that direction, and which finds its only vent in the spleen which casts slurs upon those of us on this side of the Atlantic who have been diligently engaged in furnishing this light which has been so popular amongst all classes of our people. A few years ago it was only the rich who could enjoy this luxury. To-day it is brought to the door of the poor man's house, and within a year or two more it will be the popular light which will not only take the place of the illumination by gas but will take the place of the coal oil lamp, and will be within the

reach of every one who is capable of reading and who wants light for that or any other purpose.

I now have the pleasure of introducing to you, Major W C. Moreland who will offer you the privileges of the city of Pittsburgh. Gentlemen of the Convention—Major Moreland.

Major Moreland then addressed the convention as follows :—

Mr. President and Gentlemen of the Convention : I have been requested by the Mayor of the city of Pittsburgh to give you a welcome to this city. To me it is a personal pleasure thus to speak—first, because I have a warm personal interest in all the men connected with the development of electricity in all of its branches, and because in this convention there sits a man who, 40 years ago, was my master and my instructor—taught me how to carry a telegraph line—how to make a splice ; taught me something about a magnet, a little about instruments and asked me on one occasion to go—not very far from where we are sitting—to see whether the lines were not broken between two poles, told me how I could test whether or no the connection existed between those two poles, by putting the two ends of the wire to my tongue. I did it, gentlemen, and fell over the hill. I sat opposite him when the first telegraphic communication between New York city and New Orleans passed over this part of the continent. I heard him say that he had carried the wires through the marshes of Louisana along through the whole of the south—my friend, David Brooks, the man who introduced electricity into the city of Pittsburgh and built the first lines through this region, connecting the extreme east and the extreme south. I have, in addition to that, gentlemen, a personal pleasure in asking your attention to the industries of the city of Pittsburgh. If you have leisure to examine them, they are worthy of your study, and we are glad that such a convention as this has assembled in our city. You have solved the great problem that was in the mind of Benjamin Franklin, who claimed that electricity was at last to be subordinated to the uses of man. You have brought it to our homes, you have brought it to our industries, and who can tell where with your industry, your talents, your perseverance, it may not be brought at last. It has now become not merely a commodity but a source of pleasure at our homes and fireside. Gentlemen, I have a personal pleasure in meeting you, not only because as an old electrician myself—that is to say a novice in electricity—but one who sympathizes with the progress made during the last 30 years, and secondly because you are right in the place where, of all other places, we want electricity practically applied. I know little about your purposes—but little about the progress your society has made ; but in the name of the city of Pittsburgh, as the representative of its mayor, I bid you a most hearty welcome.

The secretary read a letter from Mr. G S. Bowen, of Elgin, Ill., expressing his regret at being unable to attend the convention ; also a letter from Mr. F. C. Osborn, chairman of the committee on progress, of the Engineers' Society of Western Pennsylvania, inviting the members of the association to attend a meeting of that society at 8 o'clock in the evening.

It was agreed that the invitation be accepted, with the thanks of the association.

Mr. Duncan—I move further, sir, that an invitation be extended to the Engineers' Society of Western Pennsylvania to attend the sessions of this association during this convention, and participate, if they so desire, in its discussion. The motion was unanimously voted.

A letter was read from the Allegheny County Light Co., inviting the members of the association to visit the station of that company. On motion the invitation was accepted. A similar invitation from the Westinghouse Machine Co. was read and accepted.

A telegram was read from Mr. H. C. Davis, President of the Electric Club, of New York, tendering to the association the use of the club house in the event of their holding the next convention in the City of New York. Referred to committee on place of meeting.

A letter was read signed by several Westinghouse sub-companies enclosing a contribution by those companies of $1,150 "To encourage the best interests of the association."

The communication was, on motion, accepted with the thanks of the convention.

The secretary and treasurer read his report which, on motion, was accepted.

The report showed the following :

RECEIPTS.		
From Aug. 1, 1887, To balance....	$ 692.15	
To Receipts from Aug. 1, 1887, to Feb. 18, 1888.........	1,261.62	$1,953.77
DISBURSEMENTS.		
From Aug. 1, 1887, to February 18, 1888		982.10
Balance on hand..........		$971.67

The membership numbers 168.

The report of the chairman of the executive committee was read by Mr. Duncan, and received and ratified by the association.

The recommendation of the executive committee that members in arrears for dues shall be notified at once that they will be dropped from the rolls after the expiration of thirty days, if their dues were not paid, was, on motion, adopted.

Mr. S. A. Duncan—I submitted in writing, as provided by the constitution, and left with the secretary, an amendment to the constitution in regard to the question of dues. The dues at the present time are an initiation fee of $10 and yearly dues of $10. It is very evident to the members of this association that for some time past the association has omitted to have its reports printed, but the association has not had the funds to properly proceed with that work and to print them as they should be printed, in pamphlet form, and it is only at this meeting that our funds are in such shape that we could possibly proceed with the work. The matter had given rise to considerable debate and discussion, and in order that it might be brought properly before the association at the right time, I submit the following amendment to article 8 of the constitution : "That the yearly dues of the association shall be $20." I submit that as an amendment to article 8 of the constitution, and ask that it may lie over for consideration until to-morrow morning to be made the special order of business at our opening meeting to-morrow.

The President—Gentlemen, you have heard the proposed amendment to the constitution. Article 9 of the constitution prescribes that all amendments shall be presented in writing and referred to a committee to be appointed by the Chair before being acted upon by the association ; a two-thirds vote of those present shall be necessary to their adoption ; and that a ballot on such amendment may be called for upon the request of five members of the association. In pursuance of this provision, I will appoint as the committee on this amendment, Mr. Duncan, Dr. Moses and Mr. Weeks.

Mr. Duncan—Mr. Chairman, I desire to make the following motion which was unanimously recommended by the executive committee—that Professor George Forbes, of London, England, be elected an honorary member of this association.

Professor Forbes was unanimously elected.

Mr. E. T. Lynch, Jr.—I should like to make a motion for the appointment of a committee of five for the nomination of officers for the ensuing year, said committee also to make a recommendation as to the next place of meeting ; the committee to be appointed by the Chair. The motion was carried.

A brief report by the committee on the insulation of wires and construction of plant was read by the secretary.

A paper upon the same subject, by Professor Elihu Thomson, was read by Mr. Rice. (See page 90.)

The President—The paper is now before you for discussion.

Dr. Otto A. Moses—I have been informed that, in the absence of Professor Thomson, the President requests that I, as second on the list, shall speak to the question. I feel like quoting a passage that I think will reverberate in all your hearts : "The boy stood on the burning deck, whence all but him had fled." During the greater part of the time since the last meeting, I have been absent in Europe, whence I have but recently returned. I do not see another member of that committee. Within the last three days I received a communication from the chairman of the committee asking me for my opinion of the report which has just been read—asking my approval or disapproval. I gave neither the one nor the other, as the time was too short for him to receive my reply, and I expected to answer him at the convention. As he is not here and has kindly submitted to the convention a paper which embodies his own views on the subject, I believe that I should speak for the committee, since they appear derelict in their duty. It must be borne in mind that a committee of able men was appointed before this one was formed who did some preparatory work, but who declined to proceed further in the investigation without some funds to provide for experiments. But the President of our association, with his usual intuition, appointed a committee composed of men that had laboratories at their command. If my memory serves me, that committee consisted of Professor Thomson—we all know how admirably fitted up his laboratory is—of Professor Duncan, of Johns Hopkins' University—we know how much care and time Professor Rowland and himself have spent on their laboratory ; Mr. Hamilton, of the Western Union Telegraph Company, who has charge of the testing outfit of that company ; Mr. Lockwood, of the Bell Telephone Company, known to you all by his writings and his investigations in telephony ; Dr. Waldo, who has had several university laboratories under his command, and Mr. Shallenberger, of the Westinghouse Electric Company. Thus all the different requirements of installation would be properly represented in the committee. The committee was formed for the purpose of getting an exhaustive report. Now the reasons that have been advanced by the chairman of the committee are valid in some respects ; yet, as I only received a communication but two days before the meeting of the convention asking my opinion on the subject, I am led to believe—though I have no absolute reason for saying so—that other members of the committee may be in exactly the same position as myself. They may not have received sufficient notice to enable them to give the report the attention it deserves. I do not feel as if that committee should be discharged. I would suggest that the Chair should be requested to re-appoint

them. Every member of that committee is able to do good work, and I hope that the next report of this convention, will include a report on insulation that will be of benefit to this convention, and that will be somewhat of an honor to American electricians for its thoroughness and fullness.

Mr. DeCamp—I agree with Dr. Moses that that committee should be continued. There is much in the subject for discussion which may be brought out in a paper to be presented to the association before the close of this meeting which the members of this committee will have the benefit of. There is a great deal in the report which will be pertinent to our underground wire discussions. I will therefore move that the committee be continued as it is, to report at the next meeting of the association. The motion was carried.

Mr. Wells Leggett—I wish to point out the effect upon a lead-covered cable of a short kink in the cable or of a dent in the lead—the compression of the insulation, whereby it is rendered a shorter conductor, so that at such a point there is a better opportunity for the current to leak out. I suppose that has occurred again and again in the experience of members of the committee.

Professor Thomson refers to the potential of the alternating current and its relation to the insulation required, raising the question, whether or no, in alternating currents, the potential instead of being one thousand volts is not practically five hundred volts in respect to its action on the insulation—whether or no the insulation is not required to confine a current of five hundred volts, rather than one thousand—whether it is not an average between no current and full current, and whether that does not account for the fact, as I understand, that with the Westinghouse alternating current underground lead covered conductors have been employed with good results.

Mr. Rice—If I am allowed to answer Mr. Leggett on that point I would say it is just about the other way. The potential that the insulator has to stand on a thousand volt alternating circuit is nearly two thousand volts—just about double that of a direct current. When you say 2,000 volts it means an average of one thousand volts. Perhaps the reason we do not have any more current with alternations than the direct is that there is no active kick to speak of on a disruption of the line. Whereas with a direct current there is quite a kick.

Dr. Moses—It seems a mere hypothesis that the potential rises to two thousand volts, because, in measuring those currents—Mr. Rice will bear me me out—that he has never seen indications with an alternating current of 1,000 volts potential. It therefore appears to simply become a hypothesis.

Some further remarks were made by Dr. Moses and Mr. Leggett upon the compression of the insulation in lead covered cables by short bends.

Mr. DeCamp—I cannot claim any practical or theoretical knowledge as to this alternating current. I will simply put myself in the position of an asker of questions. I have generally understood that one of the difficulties in maintaining perfect insulation with direct currents is in obtaining insulation to cover a given number of volts and to provide against what I understand is the reactionary current arising from various causes. Dr. Moses states, and therein agrees with Mr. Rice, that the alternating current runs from zero to two thousand volts.

The President—Mr. Rice stated that the current ran from zero to two thousand volts, but Dr. Moses stated that was an hypothesis, and that there was no proof of it.

Dr. Moses—We stand as to that, as Faraday says we always should stand in the face of an hypothesis—with suspended judgment.

Mr. DeCamp—Slight intermissions of currents are sure to attend any reactionary currents which are, intentionally or otherwise, created on a circuit. It just occurred to me that this alternating current is of that nature, that is a constantly reactionary current; and hence my conclusion would be that the difficulty of insulating against that kind of current would be greater than that of insulating against a constant current.

Mr. Eustis—With regard to underground wires I wish to mention a little result that came to my notice some time since, which may be of some use to the convention. In Professor Thomson's paper he states that after the cables are once laid they are then not liable to be disturbed, owing to the mechanical covering outside. But I know of one particular case in which the insulating wires were laid in a conduit, by a railroad track, in a box about six inches square. Three or four wires were laid in that loosely. Every time it rained the water from the side of the tracks washed more or less through this conduit, and carried with it, I presume, some sand. At all events, after the wires had been laid there about two years the insulation was found to be destroyed; and on drawing the cables out it was found to be due almost entirely, as far as outside appearance went, to the purely mechanical injury. The only explanation that I can see for that was the fact that as the heavy trains went over this conduit they compressed the ground, and the cables being laid as it were suspended—owing to its own stiffness—the two wires slipped by each other and gradually chafed the face of the two wires, one upon the other, and cut the insulation through. If any one has had a similar experience I think it would be a benefit to the association if he would state it.

Dr. Moses—I would like to ask if those wires were suspended or laid on the board.

Mr. Eustis—They were simply laid loose.

Dr. Moses—But only holding their own weight?

Mr. Eustis—They were thrown into this box loosely; and they were undoubtedly full of kinks My idea is that, as the box gave from the weight of the trains, the wires being loose in the box, because of its own stiffness, would spring against one another, the two wires bending differently.

Dr. Moses called attention to several instances of the great effects of oft-repeated concussions, and mentioned as an instance of the results of the continued application of even a small force, the experiment of the bullet and the cake of wax or resin, through which it is slowly forced by the action of gravity.

Mr. Eustis—In the case that I have referred to the abrasion takes place for lengths of about six inches or twelve inches, at different places throughout the whole length of the wire, and extending a distance of something like fifty feet. There would be places eight inches in length, where the outside covering was completely chafed through, evidently from some change of that kind. What it is caused by we do not know. In other places the insulation was perfectly intact.

Mr. David Brooks—This slight jar or concussion can only be seen after a time. This matter was brought to my notice the other day by the Pennsylvania Railroad Company. They had laid three cables in a wooden box along their railroad track. The boxes are four inches square, and fastened or closed; but it was found after awhile that the cables began to give way. They opened the boxes and they found that where they were laid on the bottom board of the box the cables had worked, by reason of this jar, about half-way through the board, and it had taken the covering off, greatly to their surprise, so that the insulation was interrupted. I have heard that in London, where they run the pipes on the overhead ways, even on those made of bricks or of solid masonry, this continued jar will in time begin to affect them. So that it is well, when anything of that kind is laid, to have it away from anything like concussion, although the concussion may be but small in amount.

Mr. Sperry—Inasmuch as we have Mr. Sunny here with us today, and he has a large experience in handling high potential currents underground, and as this matter of insulation is a very important matter, and anybody who can give us light upon it should be heard, I would suggest that he give us the benefit of his experience.

Mr. Sunny—My connection with the electric light business has only been for a short period, and I do not know that I am sufficiently acquainted with it to speak on the subject. We have had some experience with underground cables, and I have made some memoranda indicating the results of our experience, which I intend to present when the discussion of underground cables comes up, as I understand it will in a day or two. I would like to state, however, in reply to Mr. Leggett's question as to the effect of a dent in a lead cable, what the effects are upon insulation. We have to-day a large number of burn-outs in our lead covered cables, and I have been investigating a few of them, and I find, as a rule, the cable has burned out at a point where the surface was perfectly true, and where there were no indications of mechanical injury. On the other hand, in pulling out cables which have been destroyed we have found portions of them where the mechanical injuries have been so great as to completely clean the lead off the insulation, leaving the lead bared. There was no indication, at the point where the lead was bared off, that any leak of the current occurred at that point. The facts that I have embodied in this short report are at the pleasure of the convention.

The President—A paper on underground systems will be presented by Mr. Leggett, and another, as I understand, by Mr. J. C. Smith; and this discussion will more properly come up after the presentation of those papers. The paper of Dr. Lange is next in order. As he is not here I would like Mr. Martin to read it. (For Mr. Lange's paper see page 100.)

Dr. Moses—At the last meeting of the association this topic was introduced as a very important matter; and we are glad to know that Mr. Lange has been able to give us a means of overcoming the difficulty which is at once so thorough, so simple and so ingenious. The other day I had occasion to speak to a friend about an experiment that I had tried on the previous evening. I was in my bedroom, and took my watch off to place it upon the bureau, where there was a little compass belonging to one of my children; and I thought to myself that I would see whether the watch, which was said to be protected by a magnetic shield, would affect the magnet. Fortunately for the experiment as I moved the watch toward one of the poles it was repelled, and thus absolutely proved that there was a permanent polarity somewhere in my watch. Had it been simply a mass of iron that acted upon the poles of the compass magnet it would have attracted it to either pole; but the repulsion was proof to me of the magnetic polarity of some part of my watch. This watch of mine has given me a great deal of concern. It was presented to me on my 21st birthday, and I will do anything in the world to demagnetize it. In 1881, while at the Paris Exposition, I mentioned it to Mr. Varley; and he very kindly took it to an Edison dynamo, and

turned it round in a way to reverse the polarity, which is equivalent to alternating the current, until he got away some distance from it; but still he did not demagnetize the watch. I could not understand the reason of this, but explained it to myself in this way: That there was a certain amount of magnetism in my watch, every part of it being of steel, and that certain of these parts were lying parallel to the lines of force at a given time, and that they attracted the magnetism, and acted upon the hair spring and balance wheel. But, to continue the statement of my experiment: I mentioned that to one of my intelligent friends in New York, and he said, "Show me that, because I believe that my watch is taken in the same way. It stopped suddenly last night, and this morning went on again." I thought it a very important matter if we could manage to get our time-pieces going regularly. So I said, "Let us see what is the reason." Said he, "I opened the case, some time ago, to see what was the matter. I found that the watch had stopped, and in order to see what was in the watch to make it stop, I opened it with my pocket knife, and perhaps my knife was magnetic." Said I, "Let us try it." So we took a needle, and floated it on a cork on water—that being a delicate compass needle with which to test for magnetism. He applied his pen knife to it but it did not work at all. So I said, "Who made your knife?" He said, "Rodgers." Said I, "I guess it is a pewter knife." "No," said he, "it is a steel knife." I looked at it, and sure enough, there was Rodgers' marks upon it. I thought that I would show him how the needle would whirl around if a magnet was made to approach it, and so I took my knife, which I knew to have been made magnetic by one of my children a short time before; and I brought that knife near the needle, but it did not budge. Said he, "I guess yours is a pewter knife." I said, "Not at all; it is a Rodgers' knife, too." I thought to myself, "How is this?" I recollected that only the day before I had been near the poles of an alternating current machine. I had not tripped over it—as a certain gentleman says he tripped over a machine, and was thrown 15 feet away—but I was merely in the neighborhood of it; and probably my knife had been demagnetized in that way. The observations made by Mr. Lange in his paper more and more impress upon me the absolutely essential character of alternating currents for all distribution of electricity where we have to depend for life, or the safety of property, upon the compass needle. I think that that paper points to the abandonment of the continuous current distribution of electricity on board steamships. That is a very broad saying; but I think it will be proven, or supported by the facts that he has mentioned, and that as soon as the attention of the owners of steamship lines is called to it they will investigate the matter and verify the statement by experiments, and that the result will be a change from continuous current machines to machines producing alternating currents. That is a most important thing, and may be the means of saving many lives. I have had opportunity recently to see something of the carelessness of the officers and sailors on shipboard in respect to handling the electric light wires when they are being moved out of the way. They do not consider the action of the currents upon the compasses. It is a most important thing that we should get rid of the possibility of the action of currents upon compasses, particularly at times of danger. I think that the paper which has been read will prove one of the most instructive to be found in our annual proceedings.

Mr. Law—I quite agree with Mr. Lange in his conclusions, and I may state that I have been considerably troubled with my watch. It has a shield on it; and I will guarantee that if placed side by side with any watch in the room it will interfere with that watch's movement. I mean, any watch not properly protected. I have had considerable experience since the time of the electrical exhibition in Philadelphia. While there I demagnetized hundreds of watches by the old process of spinning them between the poles of the dynamo; but I had to be very careful in doing that not to do it as a man did who came into the station one night, and said, "I would like to demagnetize my watch;" and he held it out to the dynamo—and soon after he had to pick it up all around the room. I went through that precise experiment last week with Professor Houston, and the remarks which he made I wish to call to the attention of those who are investigating this subject. I will not state them in detail, but they refer to the old experiment of turning a copper disc between the poles of an electro-magnet. That copper disc will produce currents, and is called, I believe, Barlow's wheel. The supposition was that although the balance wheel of the watch was made of purely non-magnetic material, still if placed between the poles of the dynamo their influence would affect the balance wheel the same as it did Barlow's wheel. The first experiment was to place the watch in the safe at the works for three weeks. It was a watch manufactured by one of our largest watch-making concerns in the country, and it was purely non-magnetic. The action was perfect. It was timed every day by a reputable watchmaker. This watch was placed on the poles of a 20-light Weston machine and remained there for five minutes without any effect. My own watch was placed by the side of it, and instantly stopped. Then the watch was placed between the poles of an Arnoux-Hochhausen dynamo—a 30-light machine. The armature was taken out, and the watch braced up by wooden blocks, so as to come right between the poles of the magnet, and directly in the strongest line of the force. We put that dynamo in a Daft circuit; the watch was placed in and allowed to remain there one hour. It lost fifteen seconds during the time. But understand, gentlemen, that the influence of the dynamo in this case was far more powerful than the watch would ever be called upon to sustain in ordinary use. I wish to call the attention of those present to this old principle of Barlow's wheel with a view of ascertaining if they have discovered any action on a balance wheel of non-magnetic metal.

Dr. Moses—I wish to call attention to an early experiment of Faraday's. He found that the needle of his compass, a short needle, oscillated too quickly. Thereupon he had a heavy brass plate put under it. The needle diminished its oscillations about one-half in a given time, showing the influence of a solid mass of metal upon it. It thus appears no mass of metal oscillating in a magnetic field will retain the same number of oscillations per second that it had before it came into that field.

Mr. Garratt—I confess that Dr. Moses has somewhat frightened me; and I think that perhaps any one who has occasion to go down to the sea in ships, and to do business in the great waters, might well feel alarmed if he were to assume that the great vessels, which are built of iron, which cross the ocean with their freight of thousands of lives and millions of dollars' worth of property, stood in any very great danger by reason of the electrical appliances which they now carry. I know nothing whatever from personal experience about the effect of dynamos and currents, and more especially the induced effect of currents upon navigation; but I am informed by a friend, an engineer of experience, and in whom I have confidence, that in some of the great ships which contain a ramification of wires, there has never been found exerted any influence whatever upon the compasses by the electric plant which lights the ship, and does a part of the mechanical work upon it. In saying that, I do not wish in any way to reflect upon what Dr. Moses says in regard to the value of using alternating currents where they can be so used on board ship, or in other places where we must rely upon the magnetic needle; but it does not seem to me wise that it should go out from this convention that the present electrical apparatus in use upon steamships constitutes an element of great danger. On board the steamship *Trenton* the curves of that ship and its magnet were worked out almost every day for a time after the electrical appliances were put on board; but no variation of the compass needle, or of the magnetism of the ship itself, or of any part of it, so far as the engineers who carefully investigated the matters, were able to discover, resulted from the dynamo plant which the ship carried. I want to again say that I do not intend that statement as a criticism or reflection upon what we all must recognize to be the very valuable remarks made by Dr. Moses; only I want to suggest that we are not in any great danger, the next time we want tocross the Atlantic, of fetching up somewhere near Sandy Hook after we have started for Liverpool, simply because we have a dynamo on board the ship.

Mr. Sperry—I would like to ask the last speaker if it is not a fact that those compasses are provided with heavy masses of metal, thus forming a magnetic shield around the compass.

Mr. Garratt—I would be most happy to inform the gentleman, but he must remember that I put a saving clause in my remarks, and that was that I knew nothing whatever about the subject upon which I was speaking.

The President—In order to reply to Mr. Sperry's question, I will ask Mr. Colvin, who was an officer on board the *Trenton*, to state what the fact is.

Mr. Colvin—On most ships the compasses are surrounded by a mass of metal which acts as a shield. In the case of the *Trenton* (and I was aboard of her for some time) I had occasion to work out the deviations of the compass, and they were worked out on this side as they were in the Mediterranean. We would swing ship and take the bearing of the sun on every point, and every half point sometimes, with the dynamo going, and then with the dynamo not going; with certain lights in, and certain lights out; with lights going in the pilot house, and lights not going in the pilot house. We had a torpedo apparatus there, of which I had charge; and the currents of that did not affect the compass at all. The ship's compass is composed of a number of needles of steel on the under side of a cardboard, and I never knew any variation in those curves that would amount to anything. The captain of the ship does not walk about the ship not knowing what his compass is doing. He knows more about that compass than he does of his own mind; and it is worked out every morning; and every morning the captain takes a sight for the longitude, and by that corrects any deviation of the compass, and so he is pretty safe.

Dr. Moses—I would like to ask our friend Colvin whether if a wire carrying the entire current from the dynamo that was competent to supply 500 15-candle Edison lamps were in that performance brought near to any one of the compasses upon which the captain depended—what would be the effect of that upon the compass—even though it might be surrounded by a very large mass of copper. Does he think that it would have no effect upon the deviation of the vessel from her course?

Mr. Colvin—In the case supposed by Dr. Moses the effect would be that the quartermaster forward, and the quartermaster aft

would notice that their compasses differed, and knowing that there was a difference the aft quartermaster would go forward and steer by the forward compass.

Dr. Moses—In case the entire crew, captain, passengers and all, are in the highest state of excitement in a dangerous emergency, is it likely that there would be at such a time any comparison of the accuracy of the compasses?

Mr. Colvin—On a properly constructed ship—I do not know how it is in the merchant service, for there they sometimes save a good deal of money by not employing competent people—but in the naval service there are usually three people looking at the compasses at once, the signal quartermaster and two assistant quartermasters.

As to your objection, I will state that in the vessels on which I have been there has never been any spar deck wiring on the upper deck; it has been done with buttons under the spar deck, and by the regulations of the department the compasses are put so far from any vertical wire, and so far from any horizontal wire; and the compass upon which they rely is usually some distance above the deck. All the other compasses could be lost or broken, and there would still be no danger on a properly equipped ship, that that particular compass remaining would vary so materially as to produce any disastrous effects. I am speaking now of the naval service; I know that sometimes in the merchant service things are perhaps carelessly or ignorantly done. Dr. Moses' suggestion is a very valuable one—about alternating currents, and one which I would take pleasure in communicating to the department, although I am not now connected with the service.

The President appointed as the committee, to nominate officers for the ensuing year, and to name the place for the next meeting of the association, the following: Eugene T. Lynch, Jr., E. R. Weeks, Frank Ridlon, H. D. Stanley, and A. V. Garratt.

In view of the acceptance of the invitation to attend the meeting of the Engineers' Society at eight o'clock in the evening, and of committee meetings to be held in the afternoon, the association adjourned until ten o'clock Wednesday morning.

WEDNESDAY MORNING SESSION, FEBRUARY 22.

The report of the Legal Committee was read by Mr. Arthur Steuart, of Baltimore, chairman, who said:

Mr. Steuart—I have the honor to make the report of the legal committee upon the question of improvements in our patent laws. The legal committee was constituted some years ago, and has been working along in an effort to arrive at some practical conclusion on the question of improvements in our patent system. We all know the intimate relation that exists between the electric lighting interests, and the patent system of this country; how closely they are related; and how much the growth of electrical interests is dependent upon the perfection of the patent system; and we all know from personal experience the serious defects and disadvantages that exist in the system as it is now administered.

Report of the Legal Committee on Reforms in the Patent Office.

In the several papers that have been presented to the association at its conventions by the legal committee, the following evils have been pointed out in the government of the patent office under the existing law and certain remedies suggested.

I. The staff of examiners in the patent office have charge of public interests of a most vital nature. They are the virtual judges of whether an inventor shall have a patent for his invention at all, and also of what kind of a patent he shall have in case they give him any.

It is therefore apparent that in order that they may perform their duties with intelligence and efficiency they must fulfill several conditions.

(a) They must be thoroughly educated in the technology of the arts and sciences and in the patent law. Experience has shown that this training can only be acquired in one or two ways—either by systematic teaching or by years of experience in the practical work of the patent office—the latter method is the one now in operation, and it results in creating a class of examiners who are undergoing the process of education at the expense of the unfortunate inventor whose case may fall into their hands. The inventors of the country have a right to demand that this system of education of examiners at their expense, be discontinued, and a system adopted that will secure to the patent office a corps of examiners who will be thoroughly trained before they enter the office, and to the inventor the examination of his case by a man fully equipped to make such examination in the best manner.

(b) Having obtained a staff of competent and thoroughly equipped examiners, they must be retained in office so that the public may have the benefit of their services through a number of years. The army and navy have long since solved this problem by the exercise of a system of education, compensation, promotion, and retirement on pay which fully secures these ends. Why should not the system so successful in one branch of the government service, be established to secure similar and equally necessary results in the patent office?

(c) The examiners should be relieved from all political influence. Civil service reform has attacked the question of political interference with patent office appointments with little success. The evils from this cause now existing are great, and call loudly for remedy. The army and navy system put those departments of the public service almost entirely beyond the reach of the politicians. Thus it should be with the patent office.

II. The patent office of the United States now occupies a part of the building known as the patent office building, the balance is occupied by other branches of the interior department.

The patent office building was constructed with money paid to the government by patentees—and when first built was large enough for the accommodation of all the departments which now occupy it as they then existed; but as the work of the patent office increased additional force became necessary, until now the officers of the patent office are crowded to an extent that greatly hampers and impedes the transaction of their business. Separate accommodations should be provided for all the occupants of this building except the patent office. The space available would then not be any too large for the growing demands of the office.

III. The acquirement of more space would enable the patent office to secure a much needed addition to the existing facilities, that is to say, a laboratory—where inventions requiring demonstration could be thoroughly tested. The members of the Electric Light Association know how great is this need. No branch of invention is based so entirely upon experiment as the electrical one, and in order to obtain a valuable patent from the department, it is often necessary to set up the apparatus and prove to the examiner by actual test, that what the inventor claims is actually true. This can only be done now at the cost of much time, annoyance and money, and when these are not at the command of the inventor, his application for patent on his invention, often a valuable one, is rejected, when if proper facilities existed in the patent office, he might obtain the just reward of his labor.

IV. When an application for a patent is made by an inventor, the consideration and determination of what rights shall be granted to him, depend; first, upon the statute law, and second, upon the interpretation of that law, by those empowered to grant rights under it, and the rules of practice, established by the statutory authority, setting forth that interpretation for the government of the subordinates, who are of necessity vested with a part of the administrative duty. It is easy to see that unless the interpretations of the statute are uniform and the rules of practice clearly defined and a uniformity exist in the enforcement of those rules, great confusion must exist and great injury result to the rights of patentees.

The rules of practice of the patent office and the decisions of the commissioners of patents are the fundamental law of the department, but great latitude is given and taken by the subordinates. Practically the examiners are the real judges of both law and fact, with reference to the questions that arise in the issuance of patents. These examiners are about two hundred in number, and it is apparent that unless the practice of the patent office and the interpretation of the patent law is clearly settled, this subdivision of jurisdiction must lead to great disparity of ruling by the various examiners. And this in fact is just the state of affairs which exists to-day.

The commissioners of patents are appointed by the President, and are chosen almost invariably for some reason that has no connection with patent law, and in fact it has been many years since a man has held the position of commissioner of patents, who knew anything about the patent law or patent office practice before he took the position; and for some reason the position of commissioner has of late years not been occupied by the same man for more than two years together. So that with the directing head of the patent office, changing on an average every two years, and each time a man taking the position who is almost totally unfamiliar with the subjects which are presented to him for determination and government, it is not surprising that the examiners should be at sea with reference to the law, and the inventor and his solicitor in a hopeless state of uncertainty as to what kind of a patent can be obtained or what rights are granted under it when secured. Two quasi courts exist in the patent office: the board of examiners-in-chief and the examiner of interferences, and from each of these appeals lie to the commissioner of patents. These officers are constantly changing and their rulings are subject to great fluctuation.

It is the universal voice of almost all those who have examined this question, including the commissioners of patents themselves, that a strong permanent court should be established in the patent office, the judges of which should hold office during good behavior, and who should be chosen from among the prominent patent lawyers of the country or promoted from the ranks of the patent office examining corps. In this court should be vested the jurisdiction of the commissioner of patents, the board of examiners-in-chief, and the examiner of interferences. The decisions of this court should be published and would become the law of the patent office. Such a court being permanent and being controlled by its own precedents would soon crystallize the practice into thorough working shape, and embodying in itself the jurisdiction now subdivided among many officers, will ensure a uniformity of decision among the several branches which does not now exist. Such a court would relieve the circuit courts of

the United States of much of the patent litigation now cast upon them. A reference to the report of one of the commissioners will suffice to illustrate our meaning. The following is from the report of commissioner Montgomery of 1887:

"Aside from the burden which this imposes upon the head of this office, there is a want of uniformity in the decisions which emanate from time to time from the respective commissioners of patents, which ought to be corrected. I know of no better way to correct this evil than the establishment of some tribunal to consist of at least three judges, whose tenure of office shall be fixed, and to whom all appeals shall lie. I have no doubt that the establishment of such a tribunal with such jurisdiction would not only make it possible for the commissioner to conduct a more successful administration of his office, but would secure to inventors and to the public a much more intelligent and uniform exposition of the law of patents and of the important questions which now of necessity must be determined so hastily.

"I again invite attention to this subject for the purpose of asserting that my experience of the year last past has not only confirmed me in views which I then expressed, but has made much more manifest to me the necessity for some legislation of this character. A court of sufficient dignity and strength ought to be created, and such tribunal might very properly be invested with final jurisdiction in all matters pertaining to the patentability of an alleged invention as well as all matters of interference between litigating applicants. Such a court with such jurisdiction would not only result in leaving the commissioner free to attend to the other pressing duties of his office, but would inevitably relieve the federal courts of much of the litigation upon these subjects with which they are now burdened."

Mr. Steuart continued as follows: I have thus presented to you some views with reference to the desirable changes and additions to the existing patent laws, which we desire to secure; and I have endeavored to show you the ground upon which are based those views.

I must also make a report of the work of the committee which I have had in hand during the last six months, in attempting to bring about the results which are here outlined to some extent.

At the meeting in Boston, held last August, the association passed a resolution authorizing the legal committee to introduce into Congress a bill providing for the creation of a commission to be appointed by the President of the United States, whose duty it should be to revise the existing patent laws, and report a bill to Congress at its next session providing for such changes as they might think desirable. In pursuance of the preparation of that bill, and in looking over the ground to see whether the course was a desirable one, I was met on every side by the earnest opposition of the ablest and most careful lawyers in the country, those most interested in the patent system, and they came to me with this proposition: They said, "You are doing a good work; you are in a good line; but there is an evil that we cannot escape; there is an opposing force that we must consider, and that is a deep-rooted opposition to the patent system as an element in our national policy that exists in some parts of this land. That opposition is represented upon the floor of Congress by a great many members; and any bill which is introduced of this kind, opening the door wide to revision, may have the effect (and the danger is an imminent one) of giving opportunity to these enemies of the patent system to come in and do it harm." As the result of that advice (and I found the sentiment which prompted it very general) the committee determined to change its course of action, and not to introduce that bill, but to frame another. The question of what that other bill should contain has occupied the mind of the committee up to this time. It has not been fully determined, but it will be very shortly. For the purpose of arriving at a solution of that question, and determining what that bill should contain, and for the purpose of interesting the members of the association in the work of the committee, the committee entered into personal correspondence with every member of the association and also with every person whom they could find who was directly engaged in the electrical business. I think that I do not speak too strongly when I say that they have been corresponding with not less than one thousand people throughout the country, and we have by that means been able to gather a mass of valuable information. The committee published a pamphlet, 2,000 copies of which were distributed among the members of the association, the members of Congress, and among others who were interested in the subject. They have more lately published another pamphlet, 1,000 copies of which have been distributed throughout the country, the purpose of which was to interest those whom we could reach in this subject, and get their minds into such a condition that when we were ready to present the bill we would be prepared to call upon them for their aid. I go from here to-night to Washington for the purpose of making arrangements in your behalf before the committee of patents of the House of Representatives; and I have a memorandum here of several bills which are now pending before the House Committee, which it is our effort to oppose. For the purpose of looking after this question the committee have been partially instrumental in organizing in the city of Washington a bar association among the patent attorneys in Washington. That association embraces the most important men in the profession in that city; and, being on the spot, we look with great confidence to their aid in opposing anything detrimental to the patent system, and in aiding us very materially in promoting our efforts before Congress. When I presented the subject to them I found that they were deeply interested in it, and anxious to join hand in hand with us in attempting to improve the system. The meeting which will be held to-morrow will be attended by a number of gentlemen whom I have notified, from different parts of the country—from Chicago, Boston, New York and Providence—all of whom will come to oppose the passage of certain bills which are now pending before the House. One of them is a bill which provides that patents not used in manufacturing, but held to control trade, shall be vacated by due proceedings and at the instance of anybody who wants to use the inventions. A second measure is an "innocent purchaser" bill (which you are probably all familiar with) which protects a man who cannot be proved to be a fraudulent user. The third bill gives to the circuit courts of the United States the power, at the instance of a would-be user of a patented invention, to examine the patent, and determine what would be a reasonable royalty, for that would-be user to pay for the use of the patent, and to grant to him the privilege of using it without any restraint on the part of the owner. A fourth bill reduces the term of an United States patent from 17 to 7 years. There are two other "innocent purchaser" bills, and two others which touch the issue which is now troubling telephone companies, and which may some day trouble you in your electric light business,—and that is the interference of state legislatures with the right of the patentee or the owner of a patent, to control the use of it. In Indiana, the legislature has passed, as you are all probably aware, a law which limits the price which shall be paid by its citizens for the use of the telephone. That law has resulted, in many cases, in the refusal on the part of the company to permit telephones to be used at all, except on their own terms. This bill is now introduced (there are two of them) for the purpose of enabling the state legislatures to bind the owners of patents by such legislation.

All of these questions are vital questions, and they are questions which lay at the very root of the patent system. If any of these bills become laws the system will receive a very serious blow; and it is our duty in your interest to oppose their passage. At the same time that the House committee convenes to-morrow there will be a meeting for the purpose of opposing the passage of these bills, and there will be a number of gentlemen in Washington, many of whom represent the electric light interests,—the Edison company having promised to send their counsel, the Consolidated company will send theirs, and the Westinghouse companies will send theirs; and we will have gentlemen from various parts of the country all of whom are deeply interested in this question and in the effort to reform our patent laws.

As I have said, we will hold a convention in Washington to-morrow to discuss the question of exactly what is desirable, and in what particular direction we shall move. We are all of us very well satisfied that our best chance of success lies in attempting very little,—in narrowing our efforts down to one or two salient points, and concentrating upon those. The probability is that we will limit our efforts to two points only: One, will be an increase of the salary of the commissioner of patents, to such a sum as will justify a man of sufficient capacity in holding the position long enough to be able to establish some satisfactory and uniform practice in the patent office. Figures were given me the other day—I did not make the calculation,—but gentlemen of eminence in Washington who have been familiar with the office for many years, have said to me that they made the calculation, —and that the result is, that for 14 years the average time of the commissioner of patents has been but 13 months. When you consider that each one of those men has entered office with comparatively no familiarity with either the laws or the practice of the office —with some few exceptions—you can understand how perfectly chaotic must be the condition of the rulings and practice of the patent office. That will probably be one of the points upon which we will centre. A second will be to establish an intermediate court of patents, which will hear appeals from the circuit courts, and also from the patent office. This is the work which the committee now have before them.

Mr. Mason—It strikes me that it would be well to reinforce ourselves by an effort to gain the co-operation of the various societies of engineers and manufacturers, who are, if not equally interested with us, at least have a considerable interest in this subject; and who would probably be glad of an opportunity to join in our efforts.

Mr. Leggett—I dislike to arise in opposition to a measure of this character, but from the very outset of this action on the part of this association, it has struck me as a measure of doubtful expediency—a thing which we ought in a very quiet way to abandon. Now, these questions, every one of which were raised by Mr. Steuart in his report, are questions which affect not electric light companies, but the manufacturers of electrical apparatus. There is scarcely a manufacturer in the country who is not willing and anxious, perhaps, to change certain features of the

patent law; and yet I doubt very much, whether they desire the system to be attacked in a general way. We have a patent system which is by far the best in the world. There is no question about that. Canada has followed it, and has made a patent law almost identical with ours. England has followed, and has patterned almost word for word the principal sections of our patent law. Germany has followed within the last three or four years, with a new patent law based almost word for word upon ours. The result of the patent law of this country has been the development of industries of such great magnitude that it has been copied in the laws of all nations. It therefore seems to me very bad policy at this time, when there is agitation against certain features of the patent law to raise the issues which are now suggested. Many of you will recollect the action which was had a few years ago, on what was termed Bill 300; at that time, a bar association was formed in the city of Washington with a view of dealing with this matter, and I think it was never formally disbanded. That association it is safe to say, together with its ramifications throughout the country was able to collect and expend probably $100,000 in an effort to amend the patent laws. Every feature which is here raised was raised at that time, I think. The bill went into the House and into the Senate, but there was no possibility of getting it through.

This is a matter which affects the manufacturing interests solely, and not our association. It is a matter in which a hundred thousand dollars was expended not later than 1877 and 1878 in a futile attempt to amend special features of the patent law,—it seems to me in such a matter that it would be poor policy for this association, where not one single interest is involved, to go ahead and expend the little money that we have on hand to seek to carry out measures of this character. I do not believe the move reflects the sentiments of the different interests of this association.

Mr. Steuart—Mr. Leggett suggests that we are engaging in an effort to tear down the wall of protection to patentees. I am sorry if I have expressed myself so obscurely. I am sorry if I have not made my meaning clear in my effort to suggest that the whole purpose of this committee, the whole purpose of the effort which has been made, has been to build up around the patentee every safeguard and every weapon of defense against infringers that could possibly be devised. That has been our purpose solely. Referring to Mr. Leggett's suggestion as to the advantages which our system has over other systems, I wish to say that I fully appreciate them. We have got the best system in the world. and those countries that have followed us,—Germany, England and Canada,—particularly Germany, which has followed us most closely, have carried our system to the very point beyond us to which we want now to carry it. The last thing done by the German government in perfecting their patent system has been to establish a court specially for patent appeals, and to put over their patent office a man who will hold his position during a long term of years, sufficient to enable him to understand the practice and to dictate proper rules to the examiners who are under him. That is what we seek. That is all that we are now seeking. It is simply to carry forward our system so as to complete it. and put it where our imitators have already gotten theirs. With reference to the effort which was made 10 years ago to alter or amend the patent system, Mr. Leggett has suggested that an effort was made in which a hundred thousand dollars was spent, and which was unsuccessful because, as he intimated, it was impossible to make any changes. I would like to read a clause from a letter which I have in my hand from Mr. James J. Storrow, whom we all know, of the Bell Telephone Company, on that subject. He says:

"Ten years ago an attack was made upon the patent system, as you know, by an organized company of infringers. The best that my associates and I, representing a large amount of patent property and interests, could accomplish, was to agree to some modifications which we thought were wise, and would tend to remove some features of the law which we had to admit, however, were very obnoxious, and to agree in a modified form to some others that we thought would have passed in a worse form if we did not come to an agreement about them."

The facts with regard to that effort were, that it was an effort by a band of infringers who were determined to break down the patent system if they could, or to introduce features into it which would enable them to use certain patented property which they wanted to use, free of charge, and free of liability for infringement. A hundred thousand dollars was spent, but it was spent to a large degree in defense of the patent system against the attack of the infringers. At present we propose, although there are many suggestions made, but those suggestions are made for the purpose of gaining light upon what is the most desirable thing to do,—at present we propose, and have settled down to the conclusion, as I have suggested that we will do just what Germany has done; we will put over our patent office, if it can be done, a man who is thoroughly capable of managing it, and we will put an intermediate special court of patent appeals, with jurisdiction to hear the technical questions which now go into our courts where there is, in many cases at least, an entire absence of technical knowledge. We are attempting to build around the patent system and around the patentee a wall which will be a benefit to every member of this association. Indeed, I can hardly conceive how any association that has existed in this land could be more interested in the subject, or could more properly be said to be the right source whence efforts of this sort should spring than this association.

Mr. Geo. M. Phelps, Jr.—I share with Mr. Steuart his surprise that the work of this committee, or any action of the association upon it, should be regarded as in anywise an attack upon the patent system. I suppose it is quite within the truth to say that the movement was conceived and started purely with the purpose of conserving all the protection that inventors now have, and of clearing up as far as possible the obscurities that exist in relation to inventors' rights, by better methods applied to certain portions of the system as now practised. I think there can be no doubt about that. I was also a good deal surprised that any one should fail to see the very immediate and direct interest that all the members of this association, as well as manufacturers, have in this question. It seems to me that the confusion which exists in respect to the relations of many patents to one another, and consequently to the rights of various people in relation to one another, is a source of constant anxiety to nearly every one engaged in the electric light business. It would seem that the work of this committee has been fully justified, and the time spent upon it well accounted for by the results that have been reached up to this time. If I understand our position now we are expected to pass upon the suggestions made by the committee, for I suppose that the remarks of Mr. Steuart made after reading the report of the committee as presented in the printed pamphlet, are to be considered also as the report. The proposition as I understand it is to abandon entirely the idea of the creation of a commission, and instead of that to direct the energies of the bar association of Washington, supported by an expression of opinion as evidenced by a vote of this association, towards the accomplishment of two distinct measures: the creation of an appellate court, and the increase of the salary of the commissioner of patents. Both of those measures seem to be quite free from the objections which would attach to any proposal which in terms by implication should seem to have for its object an increase in the scope of protection to the patentees. I am very glad that the committee, and probably all the members of the association, or a large portion of them, have recognized the danger of introducing any measure for a general revision, or any which should seem obviously to be addressed to the increasing of the value of patent monopolies in a money sense. The present plan simply looks to conserving the rights and the protection now afforded by our patent system, by a modification of the methods of administering the patent laws. The measures suggested, as they seem to me, do not afford an obvious opportunity for attacks upon the patent system, and it would be difficult to offer amendments to either of those propositions germane to their subject-matter which could successfully attack the patent laws. Therefore, I hope the association will see fit to endorse the proposition of the committee as I now understand it to be.

Mr. Leggett: I think I may be misunderstood if it is assumed that I assume that the action of this committee is in the nature of an attack upon the patent system. I do not so regard it. I think that the recommendations of the committee, in most respects, are good, and that they will correct abuses in the particular channels indicated. The point with me is simply this: Is it good policy for this association to divert its funds (which are very limited) in order to carry it into another channel foreign to its objects?

The President—Up to the present time the money expended by the legal committee has not been taken from the funds of the association, but has been contributed through voluntary subscription by the representatives of different interests; and there is now remaining of that special fund about $250.

After some further discussion by Mr. Garratt and Mr. De Camp, chiefly touching the question of expense to the association, the President asked Vice-president Weeks to take the chair, and took the floor.

Mr. Morrison—I do not discuss the legal phases of this question, nor any of those outlying ramifications which have been discussed by some of the gentlemen who have spoken. I wish to call attention to the point, which has not been adequately presented, that the men who are using electric light patents, the men who have paid their money for these patents, have found them, in a great many instances absolutely worthless. Now, there were patents and there are patents; and while Mr. Leggett has held up to you the wonderful success of the Bell Telephone, which I believe has had more piratical attack upon it because of its success than any other patent ever obtained in this country, while he has held up this thing, he has brought in collaterally the protection which has been afforded to our business. Now, I maintain that a proper system in the patent office (and I want you to think this over) would make a patent issued from that office just as good as gold,—if the system were right and if proper safeguards were thrown about it. I want also to make this statement, that, throughout this broad land where millions

of dollars have been invested in the electric lighting business, there have been very few, if any, favorable decisions in the courts in electric light patent suits. The result of that has been —what? It has been that the promoters of electric light companies go into various communities in which they live and persuade their fellow citizens to put their money into an electric light company. When you deal with a parent company its representatives will say to you, "We have the foundation patents; we have property here; we are not offering you a paper upon which is written down a number of set phrases and words; but we are offering to you something which is just as good as gold, because we are going to take your gold for it." But what has been the history of such enterprises? I do not want to reflect upon any representatives of parent companies who are here; but the melancholy fact stares us in the face—melancholy to those who have put their money into electric lighting companies and have got no return from it,—that infringers came into your territory and established themselves cheek by jowl with you; and the result was that you found yourself in a few months doing business for nothing, and a promised decision in court was never delivered. Decisions are seldom if ever reached in electric light patent suits. Therefore, the purchaser of the patent and invention suffers. The parent company, with much gilt-edged work thrown about the business, sells you what? It sells you these patents. Why do you buy them? You think that you are investing in a property which will bring you a good return for your investment. But what do you find? You find that there is no punishment for the so-called infringers. You find that your patents are comparatively worthless. Why is this? Surely the investor believes and has faith in his invention; surely the men who make these representations to you are in earnest; they are honest; and they believe what they tell you. But that which they tell you is not true. The stern fact is bitter experience, which has buried electric light company after electric light company. They have gone down in financial ruin, leaving tombstones all along the road shewing where the contents of men's pocketbooks have been scattered. Where is the fault? If the fault is not with the men who have urged you to buy their wares, it must be in the patent office. These are the conclusions which I come to. These are not the conclusions of the lawyer; but they are the conclusions of those who have lost their money, sinking it in these speculations—that is the word—speculations, when they thought they were engaged in a fixed and substantial business; it is the conclusion of these gentlemen who have invested and lost their money,—that there is something wrong in the patent office. I am not speaking for men who possess a patent incubator, or for the man who has a patent plow, or a patent harrow, or a patent washing machine, or a patent cider press, because I permit to each of them the same liberty of speech and action which I ask for this association and for its members individually; but I say that what we want to do is to protect our own interest as far as lies in our power, and we cannot protect them by sitting idly by. We must act. The paltry dole that you spend in aiding this legal committee,—whether it be $250 or $5,000, would be money well spent if it only succeed in bringing before Congress a discussion of this thing, so as to lay bare the impositions which have been laid upon inventors and investors, and the frauds which have been perpetrated upon men who have invested their money in patents.

After further remarks by Mr. Leggett, Mr. Foote, Mr. Duncan, Mr. Garratt, Dr. Moses, Mr. De Camp, and others, the subject was disposed of by the passage of a resolution, offered by Mr. Duncan, as follows:

"That the report of the legal committee be approved, and the committee continued without expense to the association."

Dr. Moses—We have the pleasure of having with us to-day a gentleman of distinction in electrical matters, Professor E. L. Nichols, the successor of Professor Anthony at Cornell University. I hope that the privileges of the floor will be extended to him; and I would also suggest and move that we request him to allow his name to be added to the committee on insulation, in order that we may obtain the advantages of such a laboratory as that of Cornell University. I would also suggest that the name of Mr. E. G. Acheson, a gentleman whose name has been brought prominently before the electric world recently as the inventor of a very beautiful heat transformer, be added to that committee.

Professor Nichols was elected to be an honorary member, and then by vote of the association both he and Mr. Acheson were added to the committee on insulation.

Mr. Duncan—The committee on annual dues offer a substitute for Article VIII. of the constitution. The present article reads as follows:

"The membership fee of each member shall be $10—which shall accompany the application.

"The annual dues shall be $10—payable in advance, and shall cover the calendar year."

Your committee are unanimous in recommending the striking out from that article of all requirement as to an initiation fee, and making the article read as follows:

"The annual dues shall be $20, payable in advance, and shall cover the calendar year."

In making this recommendation the committee had in view the increased expenditures of the association. A careful estimate of the cost of printing the proceedings of each session indicates that it will be about $400. For two meetings a year the cost of printing alone will be about $300, and the expenses of the two meetings for various incidental purposes amount, as near as we can estimate, to, say, $800. Therefore, we have, outside of any salary to the secretary or treasurer, a necessary expenditure of about $1600 per year. In discussing the financial condition of the association the executive committee arrived at the conclusion that the interests of the association require the continual services of a secretary and treasurer in procuring new members, in carrying out the orders of the executive committee, in preparing papers for the meetings, and generally giving more attention to the duties of secretary and treasurer than heretofore. There is no reflection intended upon the present or former secretary, who, while the association has not been able to pay them a proper salary, could not be expected to give their whole time and attention to its affairs. We estimate that in addition to this sum already stated, viz., $1,600, we should have a paid secretary and treasurer under the direction of the executive committee, at a salary of at least $1,000 or $1,200 a year. Therefore the total expenses of the association will amount, as nearly as we can calculate, to between $2,600 and $3,000 per year. We have now 178 members in good standing. An assessment of $20 per year will bring us a revenue of $3,560.

The amendment was unanimously agreed to.

Dr. Moses here rose to a question of privilege, calling attention to Mr. Acheson's connection with wire and cable business as a possible objection in the minds of some members to his serving on the insulation committee. Dr. Moses, as the proposer of Mr. Acheson's name, thought an opportunity for reconsideration should be afforded.

After remarks by the President and several members, expressing confidence in Mr. Acheson's qualifications, his retention on the insulation committee was unanimously agreed to.

Mr. Chas. A. Schieren then read a paper on "Leather Belting." (See page 112.)

Mr. H. W. Pope—I would like to ask Mr. Schieren about the wearing of the edges.

Mr. Schieren—The first belt which I made up about six years ago is still running. Before I came to this convention I took it down and had it taken apart. The belt is 28 feet 7 inches long, and it had stretched nine inches in the first three months. After that there was no further stretching. We took the belt down, examined it closely, and found no elongation whatever. It is 3½ inches wide, one inch thick, and transmits 15 h. p., under the following conditions: It connects two 38 inch pulleys, and the pulleys run at the rate of 125 revolutions.

Mr. Pope—I would like to ask what has been the experience in Europe with these belts?

Mr. Schieren—My attention was drawn to these belts while in Europe some ten years ago. I looked into the matter and thought very little of them. About six years ago I went to Europe again and looked at them and thought better of them. I thought there was something in such belts that would fill a gap in this country, and I determined there and then that I would try them here. However, other matters came up, and I did not try them until three years afterwards. In reference to the experience in Europe I will state that two years ago I was there and met several electricians, and got from them some very valuable information with regard to the use of linked belting in running dynamos. Their dynamos there are run much slower than yours here. A great many of them favor linked belts. They only use one pin there, and engineers told me that it takes four months before the pin adjusts itself to the rounding of the pulley. On the whole, they speak of them very favorably.

Mr. Pope—Another query suggests itself, and that is whether in the alternating system—running at 1,6(0 revolutions—the link belt would be preferable, or as good as others?

Mr. Schieren—A gentleman called on me and said: "Your linked belting has attracted my attention, and I would like to receive some information about it. My company would like a belt which would run a mile and a half per minute; can you make such a belt." I said that I would try to do it. I did; and I was successful. The belt worked successfully. I made it out of very light material. The belt is to-day running at the rate of a mile and a half per minute. I suppose that that is the kind of belt that Mr. Pope refers to.

Mr. F. Ridlon: I have used one of these belts, three and a half feet wide at a speed of 2,000 feet per minute. The only fault I can find with it is the stretching.

Mr. Rice—I would like to ask Mr. Schieren about the amount of power consumed by this belt as compared with ordinary belting. Does the belt itself use more or less power—I mean, for the bedding of the belt over the pulley?

Mr. Schieren—My experience in linked belting has been this, that it will transmit under certain circumstances more power than the ordinary belt. It will do it every time. In some instances we have put on an eight-inch belt and have taken off a twelve-inch belt. In some instances we have put on a twelve-

inch link belt, and have taken off a ten-inch belt; and it would not drive with a ten-inch belt owing to the difference in circumstances. So to-day I may say that we are ignorant in regard to the amount of power comparatively that they will transmit. We are constantly making experiments and improvements, and are gathering valuable information in that way, but I am sorry to say that I cannot answer your question intelligently.

Mr. Law—I would like to ask Mr. Schieren if he has had any experience, or enough experience, to determine the amount of damage that oil does to this belt, as compared with ordinary double belting. In some dynamos the belt is saturated with a large amount of oil?

Mr. Schieren—So far no claim is made in that direction. Of course you will understand that if the leather lies on the edge it exposes its fibre more than otherwise. Leather is a great absorber. I use blotters of leather in my office, because leather absorbs a fluid at once. No doubt you have noticed this on running your dynamos. It absorbs oil very fast. I think that the link belt would absorb oil more than other belts do, but that could be obviated by using a dressing which would close the pores of the exposed part of the belt.

Mr. Law—What sort of success have you had with almost perfectly perpendicular belts?

Mr. Schieren—We have had very good success. The only trouble with perpendicular belts is this—at first these link belts stretch considerably.

Mr. Jesse M. Smith—One of our greatest sources of loss of power in fast running belts—that is, in belts running 5,000 or 6,000 feet per minute—is the imprisonment of air between the belt and the pulley. It amounts to carrying the belt away from contact with the pulley; amounting sometimes to a quarter of a revolution, or a quarter of the circumference of the pulley. Experiments have been made that prove that a belt will drive more power if holes are punched through it, when run at high speed. The link belt which Mr. Schieren has spoken of, has, of course, a large number of holes through it. For that reason it is very easy for the air to escape and thus permit a much closer contact. I think it is a fact, and that it has already been proven in a great many cases that a linked belt will transmit more power for the same width than an ordinary flat belt will.

Mr. T. C. Smith—I can say, in answer to Mr. Rice's inquiry as to the bending strain of belts, that, without having made any particular examination of it, any one who has looked at an ordinary belt running at a high rate of speed will notice that the speed of the belt is not sufficient to overcome its stiffness and make it hug the pulley closely; but a linked belt will in all cases lie right on the pulley and form a true tangent to the periphery of the pulley wherever it strikes it. The flexibility of the belt is so much greater than that of an ordinary belt that the bending strain is less. With regard to vertical belts I will say that we had a belt of that kind, running 7,500 feet per minute, and we found that a link belt while running at that tremendous velocity would carry more power sticking closer to the driving pulley. In one case we used an ordinary eight-inch belt and then we tried a link belt, and it did the work admirably, but we had to abandon it for a very curious reason, and that was that when running the link belt at such a high rate of speed it caused the belt, in coming down on the pulley to make such a terrific roar that it made the engineer sick—it gave him a nervous headache. It was due perhaps to the fact that our station was only six feet from the floor to the roof, and with the 300 h. p. dynamo in a room only 20x30 the noise was prodigious. But so far as the belt itself was concerned its work was satisfactory.

The association here took a recess until three o'clock P. M.

WEDNESDAY AFTERNOON SESSION.

E. R. Weeks, vice-president in the chair.

Mr. Ridlon offered the following resolution:

Resolved that Article IV. of the constitution be hereby amended to read as follows:

The president and vice-president shall be elected by ballot to serve during the following meeting. The treasurer and secretary, who may be one and the same person, shall be nominated by the president, subject to the approval of the executive committee. The executive committee shall be chosen by ballot at each meeting, either annual, semi-annual or special, to hold office from the close of the meeting at which they are elected until the end of the meeting at which their successors are chosen.

On motion of Mr. Morrison, the resolution was laid over and made a special order for Thursday morning.

Dr. Liebig then read a paper on "Electric Motors." (See page 105.) After the reading of the paper the chairman called upon Mr. A. Reckenzaun for his views upon the subject.

Mr. Reckenzaun considered the paper of much interest to men who are fond of mathematical problems, but he thought that members of the National Electric Light Association have little time and less inclination to devote themselves to purely theoretical investigations. The formulæ given by Dr. Liebig are too complicated for practical use, and they involve numerous constants which can only be determined by costly experiments. Such formulæ may be very useful for comparing the relative merits of different machines after the same have been constructed and tested, but for the purpose of designing motors or dynamos we require simpler and more practical methods. Mr. Reckenzaun preferred the reasoning first expounded by Gisbert Kapp, and originally published in *The Electrician*, of London, a few years ago; the speaker explained the methods by the aid of simple formulæ and sketches upon the blackboard, and referred the audience to Kapp's book "On the Electrical Transmission of Energy," for detailed description.

Mr. H. McI. Harding—Coming to certain practical points, we want to know how much money we can make by selling electric power. Now possibly a few figures which are the reports from about 80 stations which are now selling the electric current for power may be of interest It is impossible to fix a price for any motor of any given size. That is to say, you cannot take a five h. p. motor and charge $500 a year, That, you will see a little later, is not possible. All of you in trying to sell electric power have met that difficulty. The first thing to do is to divide all the classes of industries you intend to supply, say, into two or three classes: First, constant use. If you are running a ventilating plant and charge about $120 for one h. p., that is constant use. You take next such things as printing offices and machine shops—all work of that kind, which we call partially intermittent. In that case the price has been established—and it would be well, I think, to have a price throughout the country in order to settle difficulties as to what the price of power should be, because the company seems to think that the one who is selling the motor wishes to have a very low price, and the one who is selling the motor thinks the company wants more than it is worth. First, be sure to sell the machine to the customer. Where motors have been rented the result has not been satisfactory. It has been tried by gas companies. Steam companies have tried renting steam engines, but the engines are never cared for and are in wretched condition, and the same will be true of electric motors, and the repairs of the machines after they have been run for a long time—not oiled and neglected—will more than eat up the profits. Take a half horse-power motor; the average price seems to be $75 a year. Of course that is 10 hours' service. That would be equivalent to about two cents a day, which for sewing machines is not high. One horse, $120; two horse, $200; three horse, $270; five horse, $425; seven and a half h. p., $600; 10 h. p., $750, and 15 h. p. and up, about $70 per horse-power per year. If you sell 15 h. p. at $70 a year, the intermittent use will show a large profit. These data we have obtained in this way. On every machine running on the constant potential circuit of the Edison company in New York—also in other places—they put a meter and they examine the meter at the end of each month, and that data has been of great value, because we know exactly how much the customer is using. Take the third class, which is the elevator work, you will find that to be a very profitable source of income. In elevator work for a five h. p. motor you charge $300 a year; for a seven and a half h. p. motor $360. You can charge say, about $400 for a 10 h. p. Suppose a man puts in a motor of five h. p. for a small freight elevator—if, however, he has a very large platform he can use 10 h. p. once to take up a load—you will find he is not using so much current. Now from actual tests they have found in New York that on a freight elevator charging at lamp rates, which is one and one-fifth cents for six c. p. per hour. That is equivalent to $312 per h. p. per year. The actual amount used very seldom exceeds $150 a year, which shows a very handsome profit indeed. If you calculate that you are selling your power at the same rates as you are selling the lights, then if you can make 10 per cent. by selling your current for four hours per day, if you can sell current for 10 hours a day you are making two and a half times as much, or 25 per cent. possibly. These figures may help some of you in establishing the rates which you shall charge for power. [Applause.]

Mr. Wm. Lee Church then read a paper on "Independent Engines for Incandescent Stations," followed by Mr. J. B. Edson with a paper on "The Economic Value of Steam Pressure Records."

Dr. Moses—I would like to ask Mr. Church what is about the average size of independent engine that he would recommend.

Mr. Church—The question is not governed by the size of the engine. It is governed by the size of the dynamo, and that in turn is governed by the nature of the circuit which has to be laid out. You have got to discover what your distribution of light is to be, then adapt your dynamos to that; then adapt your engine to the dynamos. Without professing to have any knowledge whatever of the economies of station management, it seems to me that a large station will naturally run in the direction of uniform sizes of dynamos throughout, for the one reason that that involves simply the carrying of one line of spare parts, and more ready interchangeability. Of course, in a station in which the light fluctuates as much as in this that I show, the smallest dynamo should be adapted to the minimum load that obtains over the greatest length of time. But I should determine as far as possible what my minimum load was to be, make that my smallest unit, and after that bring all the subsequent units to the same power, or, if found better, to still larger units, as indicated here.

Mr. T. C. Smith—Mr. Church's paper is limited to incandes-

cent stations. The use of a small engine in arc stations has been very often condemned. In an arc station you know about what your light is going to be. If you know your load is going to be 500 h. p. you can stop your engine at pretty nearly its full load. There the big engine is undoubtedly the more economical. But in an incandescent station there is no regulation as to the amount of load. We must keep that point clearly before us—that this discussion is limited exclusively to incandescent work. There are comparatively few incandescent stations that are running with shafting. Most of them are running with independent engines.

Mr. W. C. Kerr—I wish to draw attention to a point that has been called to the attention of the association every time a power discussion has arisen, and I do not see the need of mentioning it again except for the fact that there seems to be a confusion between the questions of large *versus* small engines, and subdivided *versus* non-subdivided power, less a question of size than of subdivision.

Mr. J. M. Smith—Mr. Church spoke about the economy of small engines as compared with large ones. He is perfectly right in that. But I think that the question might be carried a little bit farther. The high speed engines, as a rule, are not as economical in coal as the larger engines, for the reason that we cannot get as perfect expansion; we cannot get as good compression lines on a single valve automatic engine as we can on an engine with four valves, as in the Corliss type. But there is another means of getting at that economy which is due to high expansion, and that is in compounding. It is known that all the ocean steamers now are run on triple compounds; that is, the steam is taken at high pressure in one cylinder and expanded into the second cylinder and from the second into the third, and the very highest economy that has yet been gained has been attained with those engines. Now the same thing can be done with the high speed automatic engines which we are now using for electric lighting, and with very great economy; and the tendency, I think, which has already started in Europe is coming to this country and we will very shortly have economical high speed and constant regulating in the engines for direct running of dynamos. I understand that several of the prominent engine builders are now bringing out compound engines for high speeds, and I think the economy that has been talked about for the large slow speed engines will be met in that particular very shortly.

Mr. J. M. Smith, Mr. Kerr and Mr. Rice here spoke further upon several features of the subject.

Mr. Church—I said that the smallest unit of power should be adapted to the lightest load. I think there is but one way to settle the question as to which method is the most economical, and that is not from theoretical conditions, but from the results of those stations which operate the two systems, and extend it into the cost of the various items per lamp hour. That will settle it. Every well managed station has its nightly report sheet. Extend the one item of coal alone out to its course per lamp hour. That will give the relative coal economy; but that is not enough. Then you must extend the collateral items of repairs and all these various items extended out per lamp hour, and then you can combine them and ascertain what the grand total is as to the question of direct or countershafted engines. Anything short of that is argument and not demonstration.

Mr. A. P. Wright—I have recently taken charge of a station in New England where we are using large engines with countershafting. We are using somewhere near five and one-fifth pounds of coal per horse-power per hour, which I attribute in a great measure to our want of subdivided power. Of course there we have an extreme case. But it will not be an extreme case in the future. On Saturday night only do we have an ampere line that approaches anywhere near Mr. Church's illustration. On the ordinary week days our stores close at 6 o'clock, so that our highest ampere line is maintained for a short time only, and then very rapidly falls.

Mr. T. C. Smith—Has any one noticed this peculiarity of our service in Pittsburgh? If it is dark for an hour in the morning, between 9 and 10 o'clock, our ampere curve will jump away up. No matter how bright the day becomes after that, it does not drop much.

Mr. Kerr—Mr. Church's paper mentioned the difficulty of running incandescent lamps from very slow speed engines on account of the fluctuation from revolution to revolution. That is a thing which can be observed in a great many places. Another point is closely related to that. It is well known that a slow speed engine has comparatively small friction. If I now put fly-wheel enough on a slow speed engine to prevent the flickering of the lamps you will find that it has a very large friction. The reason that a slow speed engine has small friction is because it has not fly-wheel enough, and the number of tons of fly-wheel to give it good regulation makes it a high friction engine. This point is very little thought of in electric lighting, till too late, when a change of fly-wheels has to be made.

Mr. S. E. Barton here read his paper on "The Relation of Electric Lighting to Fire Insurance." (see page 95), and was followed by Mr. G. W. Parker, with a paper on "What Constitutes a Good Carbon Point." (see page 111).

Owing to the lateness of the hour discussion of these papers was deferred, and the session was adjourned till Thursday.

THURSDAY MORNING SESSION, FEBRUARY 23.

The secretary read the following proposed amendment to the constitution.

Resolved, that Article IV. of the constitution be hereby amended to read as follows:

"The president and vice-presidents shall be elected by ballot to serve during the following meeting.

"The treasurer and secretary, who may be one and the same person, shall be nominated by the president subject to the approval of the executive committee.

"The executive committee shall be chosen by ballot at each meeting, either annual, semi-annual or special, to hold office from the close of the meeting at which they are elected until the end of the meeting at which their successors are chosen."

The proposed amendment was discussed at some length by Mr. Ridlon, Mr. Morrison, Mr. Leggett, Mr. Mason, Mr. Weeks, Mr. DeCamp and Mr. Phelps, and was, under a ruling of the President, referred to a committee to be reported upon at a later session of the meeting. The President appointed as such committee, Mr. Leggett, Mr. Weeks and Mr. Duncan.

Mr. T. C. Smith—I have much pleasure in announcing to the members of the convention that we have made an arrangement with the officers of the Philadelphia Gas Co., through Mr. Westinghouse, to have their stand-pipe at 36th street lighted at seven o'clock this evening; and members who have not seen it will find it of interest. I may say that it is equivalent to the lighting of one of the gas wells. For those who wish to visit it cars will be in waiting at this hotel at 6.30.

Dr. Moses—It is perhaps out of order, but just suspend your judgment for a while to enable me to offer a recommendation to the committees that have been appointed by the Chair. A committee is supposed to express the feeling of the body from which they are severed for the time. It is a concentration of action for the purpose of subsequent general discussion. I would therefore ask these gentlemen of the committee who have been appointed to consider the amendment of Mr. Leggett, to bear in mind that we have been going along successfully since the founding of this association under one leadership. (Applause.) If we have been successful it is very largely due to his discretion, and to his continuous government of this body. He now finds the burden a little irksome. But, we may still want him as a wheel horse; there is no telling. Therefore, I would ask that committee to please consider seriously, whether it is advisable in any way to hamper by precluding our re-election of such a man when the time may come that it shall seem desirable. Circumstances may arise in which it may be necessary or desirable for us to have the leadership of one president continued. Therefore, I think it would be wise to consider very carefully whether we should hamper ourselves at any time when we get a good man in office.

I am requested, Mr. President, by E. G. Acheson, the gentleman who was elected yesterday a member of the committee on insulation, to express his thanks to the convention for the honor done him, and to say that while he is perfectly willing to give us the benefit of his experience in such matters, still the fact of his occupying a position on that committee might be misinterpreted by other gentlemen who are connected like himself with wire interests, and therefore, while thanking the association for its action, he respectfully declines the appointment.

The President—Ordinarily the appointment of a gentleman upon any committee would be directly in the hands of the President; and the necessity for a resignation would not exist. Mr. Acheson was paid the high compliment of having been elected to a place on this committee by the direct and unanimous vote of this association; and that is a compliment which was never before paid to any gentleman in the history of the association. It is with the deepest regret (you will excuse me for speaking from the chair, that was one of the rights I reserved to myself when you made me president in Chicago) that I find that the association is now about to lose the services of a man so eminently capable of acting on that committee, and of giving intelligent and useful assistance to this association. I hope, although he leaves the committee, he will not deprive us of those services which he is so eminently fitted to give.

Mr. Acheson's resignation was accepted.

Here followed a group of papers, which, by previous arrangement announced by the President were to be discussed together.

The papers were the following:

"The Distribution of Electricity by Alternate Currents," by Mr. T. Carpenter Smith. (See page 103.)

"The Energy of Alternating Currents," by Mr. O. B. Shallenberger. (See page 101.)

"The Undergrounding of Electric Arc Light Wires," by Mr. W. W. Leggett." (See page 91.)

"Underground Conductors for Electric Currents," by Mr. Jesse M. Smith. (See page 94.)

DISCUSSION.

The President—The four papers are now before the association

for discussion. I would suggest that the first pair be now considered—the practical side of the alternating current system.

Dr. Moses—I have the pleasure of announcing to the convention that we have with us one of the most distinguished electricians of England, Professor George Forbes, to whom the courtesies of our associations have already been extended. I hope that he will give us his views in the discussion of these various papers

The President—The convention will be pleased to hear from Professor Forbes.

Professor Forbes—While I appreciate the honor you give me, I feel that on the particular points which have been raised at the present session there is not a great deal that I can say which would enlighten the people in America as to what has been done in Europe. At every step as I go through your different cities I see how enormously ahead you are over us in England. In large part, papers which have been read have referred to the question of insulation, and as to the laying of overhead and underground conductors. Our experience in England, of course, as to underground conductors is absolutely nothing almost, for the simple reason that our people will not allow us to put our conductors underground. The public in England have a strong feeling that there ought not to be any overhead conductors; they would not allow wires on poles as you have them here—which is a very cheap and convenient method; and our telephone wires have hitherto been carried from roof top to roof top—standards being erected on the roofs; and there is a general feeling among the public that electric light wires ought not to be overhead and ought to be underground. An electric light company also feel that they would prefer to put their wires underground. The opinion seems to be different over there to what it is here. The idea in England is not so much to make a small outlay at the start, as it is to make an efficient system—a system which it will be economical to work afterwards. It is the general opinion of a great number of companies that the best arrangement could be got by underground work. However, Mr. Chamberlain, in 1883, thought it wise to practically prohibit electric light companies from putting their wires underground. The consequence was that for several years after that it was absolutely impossible to start a central lighting station. At the present moment the demand for light from central stations in England has become so great that the companies who are capable of doing the work are determined that they will satisfy the public demand; and the consequence is now that at the present moment central stations are being started in London and in other towns, but always on overhead systems. That is what the government has driven the electric light people in England to. I may mention that the insulation which is used in electric lighting overhead work in England for the alternating current, where 2,000 volts are used, is very superior to what you are using over here. The best possible insulation, of India-rubber and tape of several servings, is being used in the central station lighting which is done on a large scale there, viz., from the Grosvenor Gallery in London. I have always thought that that was very wise; but I must say that from inquiries here among those who have been using alternating currents of high potential I find that a less expensive wire is certainly doing admirably, and I think it is just possible that we have perhaps overdone the matter in England in the way I speak of.

I cannot speak upon the subject of Mr. Carpenter Smith's paper on the alternating system here. It is a most valuable paper, and one from which I myself have learned a great deal, and have taken numerous notes for our benefit on the other side of the water. With regard to Mr. Shallenberger's very interesting paper, I may say that I think those experiments which he has described are very beautiful indeed. I have been lately much occupied with the theory of alternating currents. The chief point which he has brought before us is this,—that you must not try to get at the work which is being done on an alternating current circuit simply by multiplying the volts by the current; because there is a difference between the available current and that implied by the expressed electromotive force. As matter of fact the formula comes out very simply indeed,—that the true work is really the product of the electromotive force multiplied by the line current. That is, the electromotive force as measured by the voltmeter multiplied by the co-sine of the difference of phase between the current and the electromotive force. It is a very simple thing, and it will be easy to get at the figures which give you the value of the co-sine of that angle pretty easily; but it involves a little mathematical work, and this is hardly the place for that. I have communicated this formula to the Society of Telegraph Engineers in London, since my departure from London; and it will probably come to those who are interested in applying the formula to practical work.

I do not think that there is any point on which I can give information here; but I shall listen with great interest to the discussion. Since the subject of alternating currents has been brought up I wish that somebody had given us a little information about a question which has been occupying my attention so much during the last year in connection with alternating currents—the question of meters. I would like to hear what has been done in the matter of meters for alternating currents; because it strikes me there lies one of the chief difficulties in the practical working of central station lighting. Having my own idea of the solution of the difficulty, I would like to have heard here from other people what the complete solutions are or else what are wanting. I think that would have added to the interest of the discussions on the alternating currents. I am sorry that I really have nothing to give you that would be of value to the association.

Dr. Moses—With regard to the question which Professor Forbes asks—about the measurement of alternating currents by meters—it is of course a most important question, and one lying at the very root of all electrical distribution.

Now, we come along to another period, when people had become familiarized with the handling of currents, and it has been desired to use the alternating currents for illuminating purposes. The alternating system has now been successfully introduced, but that link was wanting which the far-seeing mind of Mr. Edison supplied in his particular system of distribution by the electrolytic meter—the meter for the registration of the quantity of current consumed. Every one is familiar with the gas meter; every one knows that while it is somewhat unreliable, it may tell the truth; it generally does not; but still, it is a something. Now, in the alternating current distribution there has heretofore been no such thing. I am glad to say that I have had the privilege to inspect every part of the Westinghouse establishment during the past two days. And, among other things, I have seen a meter which I would take occasion to mention here as being one most admirably adapted to the registry of alternating currents, and with this excellent quality, that it will speak the truth, and with this corrolary to it—that we can verify it ourselves. I have to speak guardedly of this, because I was told at the time, that, while it was shown, still for certain reasons connected with the taking of European patents, and such things, it was not desirable that the particulars concerning it should be promulgated.

Mr. Lockwood—I would like to ask Professor Forbes a few questions with regard to underground wires in England. In 1881 and 1882 I had occasion to be in London, and investigate somewhat while there the underground wires of the arc light company—of two companies especially—and they were the Brush company, operating the Brush system, and the Electric Light & Power Generator Company, of London, operating the Weston system. I understood while there that within one year's time the Brush company were forced to renew three times their cables which they had laid down at Cheapside, in the lower part of London, and that each time they put in the kind of insulation that Professor Forbes speaks of as being preferable in England—the India rubber insulation; their cable being laid at that time by the India Rubber & Gutta Percha Company. I do not remember as to whether the Weston company had replaced theirs so many times; but I think they were replaced twice. I would like to ask Professor Forbes if he can give us a few points with regard to those companies, and whether they were ultimately successful in getting a cable which would stand the potential.

Professor Forbes—I cannot answer that quite fully. I can support your statement regarding the failure of the Brush company's cables; but I do not think that the statement is correct that they were the work of the India Rubber & Gutta Percha Company. I do not think that that was the case. The cables certainly were continually developing faults in different parts, and enormous quantities of the cables had to be laid; and, even when they were working at their best the insulation on the line varied enormously with the weather; so much so that, on some days, it was really almost impossible to work them. Eventually, as was stated just now, the whole of the cables had to be taken up. The best underground cables that I know of are at the works of the India Rubber & Gutta Percha Company, where they have had their cables lying for about six years, and are serving the whole of the arc lights in their large works. They are laid in a conduit, which, however, is not water tight, and the cables in some parts are dry, and in some parts are wet, and in other parts are alternately wet and dry; and they really undergo serious changes by the action of the water, as might be expected; and yet they have been maintained admirably during the whole of that time. I think that is all the information that I can give on that subject.

Mr. Morrison—I was not present when Mr. Leggett read his paper, and am not familiar with the details of it; but I wish to say this: Be careful how, as an association, you deal with the question of underground wires, and also be careful how you put yourself on record by taking the ground that such a plan of laying wires is not feasible. I do not intend to take any part in this discussion either pro or con. Of course I am opposed to underground wires. So is every man who has money invested in electric lighting. There are a whole lot of things that we are opposed to, but the reasons why we are opposed to them would not look well in print.

SESSION OF THURSDAY AFTERNOON.

The secretary read a communication from Mr. Benjamin Rhodes, manager of the Brush Electric Light Company, of Niagara Falls, inviting the association to meet at Niagara Falls next summer.

The committee on amendments to the constitution submitted the following report:

The committee on amendment of the constitution respectfully recommends that Article IV. of the constitution be amended to read as follows:

ARTICLE IV.

The president and vice-presidents shall be elected by ballot to serve from the close of the annual meeting at which they are elected until the close of the next annnal meeting, and the same person shall not be eligible for the office of president or vice-president for two successive terms.

The treasurer and secretary, who may be one and the same person, shall be nominated by the president subject to the approval of the executive committee, which shall have power to fix a proper compensation for his services, subject, however, to the approval of the association. The executive committee shall be chosen by ballot at each meeting either annual, semi-annual or special, to hold office from the close of the meeting at which they are elected until the end of the meeting at which their successors are chosen.

W. W. LEGGETT.
E. R. WEEKS.
S. A. DUNCAN.

Mr. Mason, moving that the report be laid upon the table, said: It is desirable, in the opinion of a number of the members of the association that several amendments should be made to this constitution, particularly, I might say, regarding the last article, which allows what seems to some to be rather loose action, namely, that amendments may be presented and acted upon at the same meeting of the association. But without particularizing further I have made this motion in order that we may have this whole question of the constitution brought before a competent committee who shall have time to consider it fully and report after due deliberation, that we may also have time to think the matter over and act consistently and intelligently.

The President—Before calling for a vote on this, I beg to remind you that in my judgment amendments should only be acted upon in full meetings. You have under consideration now a matter of the greatest importance to the future success of the association, and while I lay down the robes of authority so far as the presidential chair is concerned, yet I expect to be around when the other fellow is in the chair, and I would like to have a full expression on all matters of this kind, and I hope that neither Mr. Mason's notions nor Mr. DeCamp's suggestion shall be allowed to pass unnoticed. I beg that you will discuss them, turn them over and over and see how they look.

The motion to lay the report on the table was agreed to.

The President—The motion having been carried, the report of the committee will be the special order upon the first day of the reassembling of the convention.

Mr. Mason—I now move that a committee of five be appointed by the Chair on revision of the constitution.

The motion was carried, and the Chair appointed as the committee, Mr. Mason, Mr. Leggett, Mr. Phelps, Mr. Stanley and Mr. T. C. Smith.

Mr. Smith, declining on account of pressure of business, the President named Mr. Porter in his stead.

Mr. DeCamp moved that the salary of the secretary and treasurer be fixed at $900 dollars per annum.

The motion was agreed to.

The committee to nominate officers presented their report through Mr. Garratt, naming, for president, S. A. Duncan of the Allegheny County Light Company; for first vice-president, E. R. Weeks, of the Kansas City Electric Light Company; for second vice-president, A. J. DeCamp, of the Brush Electric Light Company, Philadelphia; for executive committee, Dr. Otto A. Moses, electrician, New York; chairman, J. Frank Morrison, Brush Electric Light Company, Baltimore; E. T. Lynch, Jr, United States Illuminating Company, New York; Frank Ridlon, of the Baxter Motor Company, Boston; W. L. Strong, of the Brush Illuminating Company, New York; T. C. Smith, of the Keystone Electric Light Company, Philadelphia; E. F. Peck, Citizens' Illuminating Company, Brooklyn.

The committee (to whom was also referred the place for holding the next meeting) recommended in their report that the next semi-annual convention be held in New York.

Mr. Leggett—It seems to me before voting for the executive committee, the question of the locality of the next meeting ought to be considered. If it should appear to the association that it might be desirable to have this meeting at Cincinnati, then, under our practice it would be desirable to have the chairman of the executive committee in that vicinity.

The President—I was going to say that if there be no objection the secretary will cast a ballot for president, and so along down, as you can only vote on one of these matters at a time. Are there any other nominations to be made than those made by the committee? There appear to be no further nominations and no objections to the vote ballots being cast by the secretary, so you can cast the vote.

The secretary then cast the ballots of the association, for Mr. S. A. Duncan, for president; Mr. E. R. Weeks for vice-president; for Mr. A. J. DeCamp for second vice-president.

The President—Gentlemen, I have the pleasure and honor of introducing to you your duly elected president, Mr. S. A. Duncan. He will find the office of president of this association a pleasant one if the same courtesies shall be extended to him as have been extended to me.

Mr. Duncan—Mr. President and gentlemen—I should be devoid of feeling did I not appreciate the honor you have conferred upon me, especially when I recognize that I am to succeed a man who, by his influence, as well as by the power of the gavel, which has been the only symbol of authority in this association, has welded together and made the association what it is to-day. Three years ago, in Chicago, a few representatives of electric lighting interests met and elected my predecessor, Mr. Morrison, as their president. From that time on he has continued to direct and control, with the advice and assistance of the executive committee, this association. It has grown in membership and influence until to-day it represents in its membership millions of capital and the intelligence and brains of the electric light interests of this country.

I shall endeavor, gentlemen, to bring to the discharge of the duties of president of this association, all the ability that I have. Promise is good, but performance is better, and you will be better able to decide upon the wisdom of your choice in the future than you are to-day, and I can only thank you for the compliment you have paid me and ask your indulgence for my failures and for probable inconsistencies in the rulings of the chair until such time as you have proper by-laws and parliamentary rules for your government. I have no doubt gentlemen, that you will place the same confidence and trust in the integrity of the chair of the future which you have in the past, and with your co-operation and assistance and with the aid of the retiring president, hope and trust that this association will do better, or as well at least, in the future, as it has done in the past

Again I thank you for your consideration. (Applause.)

There being no objection, the question of the next place of meeting was taken up before the election of the executive committee.

Mr. Foote, of Cincinnati, urged the selection of that city for the semi-annual meeting next August, calling attention to the Centennial celebration of the Ohio valley, to be held there from July to October, and the Industrial exhibition in connection with it, as advantages in favor of Cincinnati.

Mr. Leggett supported Mr. Foot's recommendation of Cincinnati for the next meeting.

Mr. Phelps moved that the recommendation of the committee be accepted, and that the next meeting be held at New York.

Mr. Leggett moved to amend by substituting Cincinnati for New York.

A vote being taken upon the substitute, it was defeated.

The original motion was then voted upon and agreed to, making New York the place of the annual meeting.

In proceeding to the election of an executive committee, the President pointed out that seven names were reported by the nominating committee, while the constitution provides for six.

At the suggestion of Mr. DeCamp, Mr. William L. Strong's name was stricken from that list, Mr. DeCamp stating that he had reason to believe that Mr. Strong would be unable to attend to the business of the committee.

There being no objection, the secretary then cast the ballot of the association for the following named gentlemen as members of the executive committee: Dr. O. A. Moses, Chairman; Mr. J. F. Morrison, Mr. E. T. Lynch, Jr., Mr. F. Ridlon, Mr. T. Carpenter Smith and Mr. E. F. Peck.

Discussion was then resumed on the papers read at the morning session.

Mr. E. B. Sunny—The statement was made this morning in the very excellent paper read by Mr. Leggett, that while it was entirely practicable to work telephone and telegraph wires underground, it was not practicable to do so with electric light wires. I remember distinctly that six years ago, when the question of putting wires underground in Chicago first came up, the telephone interest gathered its experts together, and in meeting assembled they each and every one of them avowed with all sincerity and earnestness that, while it was possible to work telegraph and electric light wires underground, it would be utterly impossible to operate telephone wires in that manner. The amount of crow that we have been compelled to eat in that time can be estimated upon when it is understood that there are 2,000 miles of underground wire working in Chicago to-day. As a matter of fact, the whole electrical interest opposed the measure and left no stone unturned to defeat it. The more they fought, the greater became the general clamor for the removal of the wires. The same thing occurred to which Mr. Leggett referred as having occurred in Detroit, the statements put forth in good faith and all truthfulness by the electrical fraternity, were discredited by everybody on the other side. The authorities exercised their power in its severest form by ordering the removal of every pole and wire from the public streets within a specified time. The prohibition included the entire city of forty-eight to sixty square miles, acres upon acres of which is vacant; miles upon miles of the streets of which are uninjured and sparsely settled, and alleys, in passing through which one instinctively holds his nose and breathes as little as possible.

The point that I think can be made is, that it is not the best policy to fight a measure in which the public seems to be so greatly interested, but to find a way to give them 10 or 15 per cent. of what they ask for, if in reason it can be done. I think now that had this course been pursued in Chicago, that we would now be able to string wires in the air outside of a limit of two or three square miles. Chicago has a thousand arc lights on underground circuits in the centre of the city, the greater number of which are in the districts served by the main station located on the Chicago river at Market and Washington streets. Most of the lighting is east of this point, so that twenty-five circuits, or fifty wires, run practically together for 2,000 or 3,000 feet.

When this station was established, several months ago, a conduit of twelve creosoted wooden tubes was put down to connect with the Dorsett conduit, built four years ago. The Dorsett conduit is made up of pipes having seven ducts, or holes, 2¼ inches each. Six lead cables of 3-32 inch insulation, No. 6 gauge, were drawn into the duct. Lead cables were used in preference to anything else, because of the difficulties experienced in maintaining the insulation where other makes—a good many of them considered first-class—had partly or wholly failed. Many of the conductors having no lead covering have done and are doing good service in various parts of the city, but in the business portion, where the earth is saturated with water gas and sewer gas, which circulates more or less freely through the conduit, nothing but lead seems capable of withstanding their influence. The six cables in each duct were made into three circuits—three positive and negative—and this arrangement is probably responsible for some of the trouble experienced. It was found that, although the insulation measurement of the lead cables in the conduit was very high—considerably above a megohm—and the insulation beyond the point where the lead cables ended and where some other wire was used was, say, 500,000 ohms, a short circuit would form, generally within 1,000 feet of the station, between the two sides of the circuit. The heat generated at the point of the short circuiting would melt the lead in the adjacent cables so that in one instance all six wires were rendered useless. Where this occurred in the Dorsett conduit the destruction did not go beyond the six wires, while in the creosoted wooden tubes on another occasion not only were the six wires destroyed, but the inflammable material of which the conduit is constructed resulted in the burning out of the entire conduit and the sixty cables in it. The cold weather of three months had frozen the earth to a depth of four feet, but when the street was opened it was found that the fire had taken the frost out of the earth below a foot from the surface, and that there was left for a distance of twelve feet a few charred sticks, the bare copper wires, and in the bottom some lumps of lead. Iron pipes were put in and lead cables of five-thirty-seconds insulation used—four of which were put in each duct or iron pipe. This heavier insulation coupled with the redistributing of the circuits so that positive wires are grouped and kept away from negative wires, will probably result in eliminating this source of trouble.

Looking for the cause of these burn-outs it was found that they occurred on circuits carrying as few as twenty lights, or 900 volts and 10 amperes, and on circuits carrying forty-eight lights, or 2,160 volts and 10 amperes. They generally occurred near the station, although there was an insulation of 6-32 inches between the two sides of the circuit measuring considerably above a megohm, and there were weaker places beyond, indicating that the nearer the station the greater is the liability of short circuiting.

It seems incredible that the 3-32 inch insulation around each conductor would not carry this voltage while the same make of cable of 2-32 inch carries a greater voltage in another part of the city. We could not in any instance of a burn-out find that an abnormal resistance had entered the circuit beyond the place where the burn-out occurred. On the contrary, as soon as the damage was repaired it was found that the circuit was in good order. Without being entirely at rest as to the exact cause of burn-outs, we have adopted what might be called a whip handle method of insulation—very heavy at the station and tapering towards the outer end of the circuit. This, it is expected, will enable the conductors to hold the current within them, under all conditions.

So much work has had to be done in the main route on account of the burn outs that we have had to make almost constant use of the man-holes in the conduit. We find now that these man-holes are all too small, and must be increased from 3 feet 6 inches diameter to 6 feet if possible. The suggestion is made that the latter size ought to be secured wherever possible, because of the impossibility of properly putting away the labyrinth of wires and cables that must be provided for at these points.

Mr. T. C. Smith—Our company here in Pittsburgh is probably as much interested as any in the country in aerial wires. We have a very large number of pole lines, and I do not know that we should feel inclined to take the whole of that wire down, and go underground within a year, or within two years. But it is very evident that the public demand is urgent that the wires be put underground wherever feasible, and our company has—without being asked by the city, and without any ordinances being passed to compel us—voluntarily undertaken to try the experiment thoroughly. We have seen a great many people try to put their wires underground, and in most cases which have come under my observation, the work has been done in such a manner that it is less a wonder that the cables burnt out than that they ever got current through them. As Mr. Smith, of Detroit, I think, has remarked, it is much more an economical question than an electrical one. With regard to one of the conduits of which Mr. Leggett spoke in his paper, the conduit in Chestnut street, Philadalphia, I happened at the very time that the conduit was being put down there to be connected with another company in Philadelphia which was also putting in underground conduits. The conduits which we laid were nothing but a lot of tin tubes put in a wooden box filled with pitch, and we hauled into it first-class, lead covered, insulated cables. We run them for six or seven months without the slightest hitch and without a single burn-out. At the time that the cast-iron conduit was laid in Chestnut street it was laid without any attempt whatever to keep it water-tight or air-tight. It was nothing but an iron trough in two parts, with putty along the edges. When the cables were put in (I saw a good many being put in) and in some of the cases where lead cables were used, the ends of the cable were simply ripped for two inches of the lead, the ends twisted, and three or four turns of kerite tape put around it; yet that has been cited as a dismal failure of underground wire. Now I am not by any means arguing that all wires must go underground, for the simple reason that companies that have spent an amount of money and have large vested interests in pole lines and wires and business cannot be compelled by any equity to remove the whole of that property and put it underground. In a great many cases it would be equivalent to sending the company out of business. But I do think that companies should endeavor, in the central parts of cities, where the streets are crowded and the buildings are high, and there is no doubt that the overhead wires are a nuisance, that they should make an honest endeavor to put them underground. With first-class work I see no reason why underground wires should not be successful. We have heard a great deal about the punching of holes through these cables. Any one who has had anything to do with arc light machinery knows that if you take a 40-light Thomson-Houston machine or a 60-light Brush machine and open the circuit suddenly you will discharge the field magnets into the line, and if there is any weak spot in the insulation it will go through it at that instant. We have demonstrated it over and over again. I think if the gentlemen who are trying underground wires will simply shut their dynamos down regularly by either short circuiting the armature or shunting the field circuit that they will do away with a great deal of this punching of holes in the cables. In laying down three or four miles of lead covered cables we cannot expect to find them perfect in every part. There will be pin-holes occasionally and the best inspection will not always discover them, but we have no right to assume because such things as that occur that the plan is impossible. There is not a man here present who has been in the electric business for a year who has not had a hundred cases of open circuits and short circuit on his overhead lines. The question is not whether undergound wires are feasible or not, but whether we cannot get them established with about the same trouble we took to get our overhead lines in position. I am interested in a company in Philadelphia which is running the underground system entirely. We started with a 200 volt direct current system. We knew that if we started that company the wires would have to be underground, that there were no more overhead ordinances going to be passed. We realized what we were attempting and we resolved to spare no expense to do the thing properly. When we purchased our cables from the company—they were all lead covered cables—we told that company to send us their most experienced men for the splicing and laying of those cables. We paid their expenses cheerfully. We not only had them make the joints but we watched them. We started at the station and turned the current into those lines. We ran there for six months without a trace of leakage, and then we changed over to the alternating system. We put a thousand volts into those cables, and they are running to-day and have been for nine months, without a single ground having occurred on them. We have fifteen miles of cable buried all told. We have had the question before us as to whether it would not be possible to run the alternating current in the same box with telephone and telegraph cables. At the request of chief Walker, the city electrician, we ran in the Long Distance Telegraph Company's conduit 1,500 feet of 3 conductor cable. On the two outer wires we put our alternating current, and we placed a 20-light converter into the chief's office. Into the third wire we connected his telephone, and there is not a trace of interference on it. The telephone company, of course, had given chief Walker permission to put that cable in their box, but they were a little nervous about the result, being afraid it would knock out their whole system between Philadelphia and New York. After we had been running about a week they came to us and wanted to know when we were going to start up. We told them that we had been running about a week, at which they were very

greatly surprised, and they have made no objection to the occupation of the box by us. Of course, I have had no real experience with arc lights underground—that is high tension currents—beyond the fact that when I put down my lead cables in Pittsburgh I used a 65-light Brush machine to test them with. I would not when testing them subject them to the strain of opening the circuit suddenly upon them.

I do not think it would be policy to do so. Chief Walker, in Philadelphia, is running some four or five miles of lead covered cable on his arc circuits. He has had one or two burn-outs. He had to string an air line for one section, because he could not dig up the streets, being winter. But he did not expect to put down a perfect job the first time. There is one thing I would like to ask some questions on. It has been stated that a direct current arc light cannot go underground. I do not think that the gentlemen who make that statement fully realize what a tremendous weapon they are putting in the hands of the press against them. I am not speaking now as an alternating current man, but as a member of the association, and as representing a lighting company which is interested in overhead wires in so far as they do not interfere seriously with public safety. We have proved beyond any question that the alternating current can be put underground and can be put in lead covered cables without any danger of loss of current. If the direct wires cannot go underground, the alternating can. And it may be that we shall be called upon to put in new apparatus which we do not want, simply because it cannot go underground. I think that in a case of this kind it is not the technical press we have to consider; they can realize the difficulty and danger and troubles of going underground. But it is the public press we have to consider. While they certainly do not always express public opinion they have a good deal with moulding it, and a persistent attack by the press on a lighting company will compel it to do what they desire. I think the sooner this question of underground wire is placed fairly the better it will be for all of us. I have had a good deal of consultation at various times with chief Walker, in Philadelphia, and he made the statement to me that some 18 months ago, before he would recommend the city to spend any money in the experiment, he wished to make a test of certain cable, and he got a length of 300 feet of cable. This was cut into two parts, and placed on the two poles—one on each pole of a Brush 65-light dynamo, laid in the yard of the station with the mud and water all around, and then connected with the air line. After they had run a few days a fault was developed in the cable and there was found to be a hole punched right through the insulation. I am not sure, but I think the other connection was found at the end of the wire, where it was bared to attach to the air line. The defective part was cut out and he has it in his office, and as I was under the impression that he had been using that wire in that way ever since, I telegraphed him this morning as follows: "Is the 300 feet of cable originally laid in the yard still in daily operation?" I received the answer from him: "To the best of my knowledge it is;" and I will ask Mr. Law whether that is the case or not.

Mr. Law—That cable has not been in use for the last five months at least.

Mr. Smith—Very good. Then chief Walker is mistaken. But at the same time he laid a good deal of cable in the upper part of the town, and that cable is still in use. Now the statement has been made that in Chicago the average capacity of the machines was 45 lights, and the average circuits 20 lights. I do not know—but I think the man in charge of the station has shown poor judgment in dividing his circuits.

Mr. Sunny—If you will allow me, I will explain that in one word—we have put out more circuits than the present business requires.

Mr. Smith—Exactly. I presumed you have done as I have done in Pittsburgh. I have kept all my circuits the size of my smallest unit. But the fact that the circuits and machines do not agree is no proof that it was done because the wire was defective. I would like to call on Mr. Wilber, of the Jenney company, who has laid a good deal of cable in Philadelphia; I would like to ask him if his cable is in use, and I would also like to ask Mr. Wilber to give his experience.

Mr. Wilber—I would say for the information of this association that last spring we laid over two miles of underground cable in Philadelphia, in the grounds of Girard College. We are running 47 lights on two 25-light machines. We have never experienced a particle of trouble with the cable from the time it was up to date. Where the cables came out at the top and connected with overhead wires there have been one or two grounds, leaks and lightning troubles, but no serious defect of the cable. But I am glad to think from our experience there, that there is some small grain of truth in the claim made that you cannot get as great a number of lights out of a given dynamo capacity in running underground as you can on overhead wires. With this exception I do not know that there is any serious difficulty in running arc light currents underground, unless it be that of expense, which is sometimes prohibitory.

Mr. Leggett—How long is the longest conduit that you have in the Girard College grounds?

Mr. Wilber—It is all one circuit. It is about two miles and one-eighth I should think. I do not remember the exact length. It is all one circuit of 47 arc lamps.

Mr. Leggett—You go out and come back through the same conduit?

Mr. Wilber—Yes, sir, side by side. It is the standard cable laid in creosoted boxes.

Mr. Law—I would like to ask Mr. Wilber if those conduits do not pass through passage-ways that go from one building to another, and if they are exposed in places to a very high degree of temperature.

Mr. Wilber—I neglected to state—and it is a very important matter—that the buildings of Girard College are heated by steam, and these steam pipes are carried through a brick conduit. We got the benefit of those brick conduits as far as they went from the engine room at the lower end of the grounds up to the furthest end of the building. We ran through this brick conduit, laid our wires in boxes in the conduit, and then branched out to the towers underground—laying it simply underground; and the duct is always heated in winter up to a very high temperature. I do not think there is any great amount of dampness.

The President—How much of your conduit runs in the duct?

Mr. Wilber—Perhaps from two-thirds to three-fourths of the entire circuit runs in the brick duct. Those branches out to the towers run through the ground.

Here Mr. Garratt asked permission to interrupt the discussion and offered the following:

Resolved, that the invitation courteously extended by Mr. H. C. Davis, president of the New York Electric Club, tendering the privileges of their house to the members of the association, be acknowledged, and accepted with the thanks of the association. The resolution was unanimously adopted.

Mr. DeCamp—Two papers have been read to-day on this subject of underground conductors—one for, and the other against; but there is one thing in which they both agree—perhaps two, but one in particular, and that is that we must have a perfect insulation. The second is that it is only a matter of cost. I believe that the first one is true, and no station will be operating a complete underground system until they secure that perfect insulation.

The question of cost is certainly one of very great importance. Electric lighting from central stations is now nine years old. There are organizations who have back of them probably as good business talent as ever backed up any new enterprise. They are waiting for their dividends yet. All know that the returns upon the capital invested in electric lighting have not been large. They have not been such as would justify the investment of money in a business which is likely to undergo rapid changes or rapid improvements, carrying with them a large depreciation in the value of their property. But the business which they are doing to-day is established—the prices are established—upon the basis of the cost of their present plants, and it is unnecessary to say that it would be utterly impossible for any company to go before the public to-day and advance the price of their lights. The prices of electric lights are high; they always have been; they are high to-day. They are lower than they were when they started; but they are high to-day. Therefore, you cannot advance your price. The cost of an underground conductor—those that are said to be reliable to-day—is four or five times as great as that of aerial wires. That must all be provided for.

It is claimed that expense of maintenance will be little or nothing. That I do not believe, from our own experience. I would not venture to say that until I had a very long experience.

In our lead covered cables there has been a tendency to short circuit between the wire and the lead; that shows an imperfect insulation. The lead does not protect when your insulation is imperfect. We put down a loop of 19,000 feet of lead cased cable placed in a box 6 inches square and filled in solid with pitch, joined to aerial wires, making a circuit of about 8 miles. That cable gave out once, through a short circuit between the conductor and the lead. It gave out again in the winter, the ground being frozen. Still another defect has compelled us to cut out a section between lamp posts all winter. There have been three explosions of gas in the man-holes within the last three months. Those are troubles that are purely, in my judgment, incidental to the conduit, but there has been other trouble which I think will always exist with lead cased wire, while it might not with some insulated cable without the lead.

Mr. T. C. Smith—I do not think two or three burn-outs on the first cable one lays has much bearing on the question of success of underground conduits. It is purely a question of policy for the companies. I do not believe there is a company that has a system of overhead wiring that could put their whole system underground without going into bankruptcy. The main question is can they not make some endeavor to put the central part of their wiring—in the central part of the city—underground? By-and-by I think that they will cut off a great deal of this public opposition to their wires. In Philadelphia ordinances have been passed allowing overhead wires to be put in the suburbs, but on the main graded streets of the city I think the electric light companies will find their best policy to put some of their wires underground.

On motion, duly carried, a committee on transportation for the next meeting was appointed by the President.

The following gentlemen were named as such committee: T. Carpenter Smith, of Pittsburgh; Mr. Geo. F. Porter, of New York, and Mr. Geo. S. Bowen, of Elgin, Illinois.

Dr. Moses—I have drafted resolutions which I know will meet with unanimous approval on the part of the convention. I will make no preamble because you all have in your minds whatever I would say on the subject. I will simply read the resolutions:

"*Whereas*, it has pleased Mr. J. Frank Morrison to insist upon not being re-elected to the position of President of the National Electric Light Association, which he has continuously held since its organization; and whereas, we have tacitly agreed at our successive re-elections of him to allow him to retire (as he has invariably requested at each meeting) whenever the interests of the association would not suffer by such action; therefore, be it

Resolved, That we, the National Electric Light Association of America, representing in our midst every department of electric light and power industry, express our deep regret at the decision of Mr. Morrison not to allow us to keep him at the helm, where, through many storms and quicksands, through much fair weather and some foul, he has successfully guided us to the haven where we now find ourselves; and be it further

Resolved, That a vote of thanks be given Mr. Morrison for the disinterested devotion, enthusiasm and steadiness with which he has administered the affairs and presided over the proceedings of our conventions; and that, further, we tender him our best wishes for his deserved enjoyment through a long and prosperous life, of the beautiful prospect of the great work he has done in founding, fostering and chartering the National Electric Light Association.

The resolutions proposed by Dr. Moses were seconded by Mr. Duncan, and were unanimously carried, when three cheers were given for Mr. Morrison.

Mr. Martin offered the following resolution:

Resolved, That the resolutions adopted in regard to the invaluable services of Mr. J. F. Morrison, as President for three years be suitably engrossed and presented to him, and that a committee be appointed to carry out this work and to make the presentation.

The resolution was adopted, and Mr. Martin and Dr. Moses appointed a committee to carry it out.

A vote of thanks was also given to Mr. H. Metzger, manager of the Pittsburgh Telephone Co., for the instrument placed at the disposal of the convention.

Mr. De Camp—I would like the privilege of offering the following resolutions:

Whereas, In the death of Mr. W. S. Frear, secretary of the Brush company, of Buffalo, N. Y., the association has sustained a severe loss;

Resolved, That the association hereby expresses its deep regret at being deprived of the fellowship and counsel of so young, promising and active a member, and that it further hereby tenders its sincere condolence to the many friends and the family of the deceased.

Resolved, That the secretary communicate the above resolutions to those who have been thus sorely bereaved.

The resolutions were unanimously adopted.

A telegram received from Mr. Arthur Steuart, chairman of the legal committee, dated at Washington, was read as follows: "Met the committee to-day; they are favorable to our plan."

Some further discussion on underground wires followed, by Mr. Wright, Mr. Eustis, Mr. De Camp, Mr. Lockwood, Mr. J. M. Smith, Mr. T. C. Smith, Mr. Law, Mr. Leggett and others—and at five o'clock the convention adjourned *sine die*.

THE PARIS ELECTRICAL LABORATORY.

While our own Electrical Standards Committee, instituted by the Society of Telegraph Engineers and Electricians, is apparently unable to get together the funds necessary for the establishment of a laboratory where electrical instruments could be officially tested in a manner similar to that adopted at Kew, for thermometers and watches, French electricians have progressed much better in this respect, the reason evidently being their command of a considerable fund which was left over from the Paris Electrical Exhibition of 1881. As the electrical laboratory in Paris will shortly be opened, a brief sketch of its history may be interesting to our readers. The Paris exhibition was not only scientifically and technically, but also financially, a great success, and at the close of it the general commissioner, M. G. Berger, was able to hand over to the Minister of Posts and Telegraphs the sum of £12,000, to be used eventually as a fund for the establishment of some kind of electrical laboratory. For a time the matter remained in abeyance, there being no public body of sufficiently strong position to initiate a work of such importance. But after the establishment of the International Society of Electricians, in 1883, with M. G. Berger as its first president, this society instituted a committee to report on the ways and means for establishing the laboratory, whilst the president took the necessary steps at the Ministry of Posts and Telegraphs in order to have the fund transferred to the control of the society. In due course, the secretary of the committee, M. E. Sartiaux, published a report containing particulars of various other electrical laboratories, and based upon this report the society definitely resolved to carry out the project for which the fund was originally intended. In this task they were well supported by private manufacturers, the Brothers Menier, for instance, giving them, rent free, land and buildings at No. 20, Rue Rouelle, in the Quartier de Grenelle; whilst a steam engine, a gas engine, and some electric machines and apparatus were lent, free of charge, by the respective makers. The buildings required some slight alterations, which were carried out under the superintendence of M. Dutreuil, the architect to the International Society of Electricians, but otherwise very little money was needed to complete the internal fittings of the laboratory. In consequence of this economy the greater portion of the fund is still intact, and the interest will be used to provide the working expenses. The society, now under the presidency of M. Mascart, has appointed M. de Nerville as general director of the laboratory. This gentleman is a telegraph engineer, and is well known in France for the work he did there years ago in connection with MM. Mascart and Benoist, in making a determination of the legal ohm. The programme of the laboratory is a fairly wide one. It is proposed that facility should be given to private individuals and manufacturers of electrical machinery for making researches which they could not carry on at their own laboratories or works. It is also proposed to standardize electrical measuring instruments, and to supply with each instrument which has been tested a certificate showing its limits of error; also to test electrical machinery generally, and to institute researches which the International Society of Electricians might deem of sufficient general utility.—*Industries.*

THE VIENNA ELECTRICAL LABORATORY.

The programme of this undertaking has just been issued by the Directors of the Technological Museum, of which the laboratory forms a recently added section. The work will be superintended by Herr Carl Schlenk, and is to embrace experimental investigations of dynamos as regards output, power consumed, efficiency, and other matters; investigations and reports on executed installations for lighting, power, or chemical purposes, photometry of arc and glow lamps, calibration of measuring instruments, and investigations of primary and secondary batteries. A tariff has been fixed for the work, which will presumably be required very frequently. Thus for testing a dynamo the charge will be from £1. 4s. to £4, according to size of machine; for testing a glow lamp, 16s. to £1. 4s.; arc lamp, £1. 4s. to £1. 12s.; calibration of instruments, 5s. to £1. 12s. Members of the museum obtain a discount of 25 per cent. off these charges. Where the work is of special nature, or for outside work, the charge is to be agreed upon beforehand. These fees are levied primarly with the object of covering working expenses. Any surplus is to be equally divided between the exchequer of the museum and the staff of the laboratory.—*Industries.*

ATMOSPHERIC TRAIN RESISTANCES.

Were it not for the resistance of the air, which at high speeds becomes an enormous factor of the total mechanical resistance, the possible speed of an electrically propelled railway train, might easily be made to approximate that of a projectile from a rifled gun. In view of this fact, the considerations presented by Mr. McElroy in a communication to the *Railroad Gazette*, are not without importance. He says:—

"As long ago, at least, as 1847 (Weale, London, 1847, and Glasgow Proc. Mech. Mag., vol. 2, p. 204), in making experiments on atmospheric resistance, Henry Bessemer (who afterwards invented the Bessemer process), from an ingenious apparatus arranged by him, found the front surface resistance of a car, at 20 miles per hour, 3.2 lbs. per square foot; at 30 miles, 4.5 lbs.; at 35 miles 6.1 lbs.; at 45 miles, 10 lbs. Each car added at 45 miles increased this resistance 4 lbs. per square foot, the total being, for a train of 8 cars, 18 lbs., and for 6 cars 30.5 lbs.

"The model train was then vestibuled car by car, and the result was the reduction of resistance, in the same ratio, of 4 lbs. per sq. ft. per car, the entire train, completely vestibuled, showing at 45 miles the face resistance of 10 lbs. due to a single car.

"Of course, running at speed againsta wind on the quarter-side, resistance would be affected by length, but these evidently are increased by successive openings between the cars. With the improved apparatus now at command, dynagraph experiments on vestibules for ordinary trains, if they proximately verify Mr. Bessemer's results, may lead to important changes.

"In modern practice, on the Erie canal, boats tow so much easier in *cue*, that this is now the common practice, and when they can be also vestibuled wave resistance will be greatly reduced."

THE TELEPHONE IN NOVA SCOTIA.

The Nova Scotia Telephone Co. formally took possession yesterday of the property and business of the Bell Telephone com-

pany, and the connections with the trunk lines leading to different parts of the province was effected. The toll rates from Truro and places beyond will be 25 cents for a conversation of five minutes. A toll for the shorter circuits has not yet been fixed; it will probably be 15 cents. The central office system of the two companies are somewhat different. The Bell system will be continued for the present, but as it is claimed the other company's is the most satisfactory it may be substituted later on. Mr. A. A. Knudson, superintendent of the Nova Scotia company, takes charge of the affairs, Mr. Edwards retaining his present position and the staff of employés remaining the same.—*Morning Chronicle*, Halifax, Feb. 4.

THE AMERICAN ELECTRIC MANUFACTURING COMPANY.

The manufacturing and the selling departments of this company are hereafter to be conducted by separate corporations. A new company has been formed under the title, The American Electric Construction Co., of New York, for the sale of the product of the Manufacturing company throughout the United States, excepting New England. A similar corporation will, it is understood, be formed in Boston, for supplying the New England states. Mr. Edwards H. Goff will continue at the head of the American Electric Manufacturing Co., assisted by Col. H. C. Adams, secretary and treasurer; Mr. A. R. Brown, now general manager of the Electrical Development and Manufacturing Co., in Boston, and Mr. B. H. Cook, the present superintendent of the Eighteenth street factory. Mr. Wood, electrician of the American Electric Manufacturing Co., will have his laboratory and experimental rooms greatly enlarged in the new factory, where will be concentrated the manufacturing now carried on in different premises.

PENNSYLVANIA STATE COLLEGE.

AN ELECTRICAL COURSE TO BE ESTABLISHED.

The trustees of Pennsylvania State College, at their meeting in January, 1888, adopted a four years' course in physics and electrotechnics. A new building for physical lecture room and laboratories is begun. An appropriation from the state will add considerably to the equipment for physical and electrotechnical work.

Under Professor I. Thornton Osmond, in charge of the department of physics, the course in electricity is quite certain to be adequately planned and conducted.

ELECTRIC LIGHT AND POWER.

THE EDISON ELECTRIC LIGHT Co., of Philadelphia, Pa., are about to increase their plant in that city. They will require additional boiler capacity to the extent of 3,450 h. p., and after a most rigid investigation, have decided to use the Abendroth and Root Safety Boiler, as being well adapted for electric lighting purposes. The Abendroth and Root Manufacturing Co., 28 Cliff street, New York, are now at work upon the first portion—850 h. p.—the remainder to follow as soon as buildings can be prepared.

THE WESTINGHOUSE ELECTRIC COMPANY has still a large force of workmen engaged in putting their converter system in the Hoosac Tunnel, the completion of which work has been retarded from several causes. Workmen find frozen ground and ice where excavations are to be made for conduits, extending about a mile from each portal. This is an unexpected obstacle to overcome, as observations of previous years place the frost line only about half a mile from the portals. The men have imperative orders to cease work as soon as a train is heard approaching and to seek safety in the man-holes on the sides of the tunnel. The conduits are of ¾ in. Canadian pine, seasoned three years, soaked in tar and oil compound, and painted with tar outside before laying in the trench. This excludes all moisture. The wire used is from the Standard Underground Cable Company, of Pittsburgh. About sixty miles of wire will be used for main cable and lamp connections. The lamps are to be hung on the side walls of the tunnel about six feet from the top of the rails. There will be 1,250 lamps of twenty-five candle-power each, fastened to the wall by Ahlstrom's expansion bolt. Workmen are now drilling holes for the bolts near the west portal. On account of the sulphurous gases and moisture, all metallic work on the lamps is done away with as far as possible, the remainder being securely protected.

Foreign.

Belgium.—THE LIGHTING OF THE BRUSSELS EXHIBITION.—The executive committee are making arrangements for the division of the lighting of the exhibition, the total light required being about 600,000 c. p., distributed among 1,200 glow lamps and 350 arc lamps. English and Belgian electricians are taking the principal part, French and German firms being less prominently represented. The motive power is supplied free, 500 h. p. being available for the buildings and 500 h. p. for the gardens. For the illuminated fountains, there will be a separate installation, with 100 h. p. M. Pieper, with Mr. Sennett, will take up this section. The Thomson-Houston, Edison, and Bernstein companies, M. Bouckaert, and M. Dulait will undertake portions of the lighting, for which very advantageous offers have been received. Paris and Brussels firms have undertaken the gas lighting on almost gratuitous terms.

Germany.—According to the presidential address of Dr. von Stephan, at the Berlin Society of Electricians, there are at present in use throughout Germany 15,000 arc lamps and 170,000 glow lamps, supplied with current from about 4,000 dynamos. Dr. von Stephan estimates that an arc lamp requires on an average ¾ h. p. and a glow lamp ⅛ h. p. On this basis the total horse-power employed in electric lighting throughout Germany amounts to 30,000 h. p. The Berlin gas works have also recently collected statistics regarding the extent to which the electric light is introduced in this town. It appears that 1554 arc lamps, 22,363 glow lamps, and 333 dynamos are installed. The town authorities are now negotiating for a new contract with the Electricity Supply Works, under which the cost of installation for glow lamps would be diminished by 18 per cent., and that for arc lights by 27 per cent., as compared with the prices at present charged, whilst the company undertake to pay a fine in case of failure or delay in putting up an installation. When the installation is put up to the order of the town authorities a fine of £2. 10s for every day's delay will be imposed, whilst for non-delivery of current to private consumers within four weeks after the installation is put up, the fine is £1 per day. The old market in this town was one of the first places lighted by arc lamps, but the installation has not proved very successful. The lamps were grouped in parallel series of two, and in some cases the conductor was iron wire. The buildings are very scattered, and supervision was not easy, consequently break-downs were of frequent occurrence. Now that the municipality have determined to erect new markets in the various suburbs of this town, they propose to light these by gas. It is, however, likely that better counsels will prevail, and that the corporation will adopt arc lamp installations where the lamps are in single parallel, and the potential is maintained at 65 volts.

MANUFACTURING AND TRADE NOTES.

THE EXCELLENCE of the vulcanized rubber belting, manufactured by the N. Y. Belting and Packing Company, 15 Park Row, N. Y., for use in all lines of manufacture, is becoming more apparent daily. This company who are the oldest and largest manufacturers in the United States of vulcanized rubber goods for mechanical purposes, have lately placed upon the market a superior quality of belting with smooth metallic surface for electric light purposes.

THE REPORT of the commissioners relative to the insulated electric wires on the United States steamship "Atlanta," was extremely favorable to the Okonite Co., of New York. It is reported that the Lord Commissioners of the Admiralty of England, after a trial at Portsmouth, report that the Okonite wires in use by them have proven eminently satisfactory.

MESSRS. WOODHOUSE AND RAWSON, of London, England, have been awarded a gold medal at the exhibition at Saltaire, Yorkshire, for excellence of their goods and installation work, and a bronze medal at Newcastle, for their Scharnweber arc lamps (80 lighting the grounds).

A. L. BOGART, 22 Union square, New York, announces that improvements in electric gas-lighting burners, patented to Leroy S. White, February 7th (No. 377,505), have been applied to the "Bartholdi" automatic burners. The improved "Bartholdi" automatic is a very compact piece of mechanism, and is said to be reliable and best made.

MESSRS. PARTRICK AND CARTER, of Philadelphia, send us their latest catalogue and price list (1888) of annunciators, bells, burglar alarms, etc. The list of this old and well-known house embraces outfits meeting a great variety of domestic applications of electricity—including hotel equipments for guest calls, time calls, and fire-alarms. Electric gas lighting appliances constitute a feature of the business of Messrs. Partrick and Carter. Their list of general electrical supplies is very complete. The reputation of this house dates far back among the early days of electrical business.

ELECTRIC STREET RAILWAYS IN AMERICA.

Now in Operation.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, 115 *Nassau street, New York city.*

ANTHONY AND BRACKET'S PHYSICS.

[88.]—In the ELECTRICAL ENGINEER, for February, there appears a criticism of Anthony and Bracket's Physics, in which it appears your reviewer has examined the part on electricity and magnetism from one side only, and thus failed to appreciate the excellence of the work. The book was not conceived to be of particular value to "practical workers" or to be "elementary" in the sense intended by the reviewer. Its true place is the class rooms of our technical colleges, for use in conjunction with a thorough course of lectures, which show the practical applications of the "definitions and resultant formulæ." When viewed from this stand-point the book shows great excellence in the selection of matter, and the manner in which the subject is presented. The proper teaching of this book cannot but give *earnest* students the best foundation on which to build a thorough course of electrical engineering, theoretical and practical. D. C. JACKSON.

LINCOLN, Neb., Feb. 6, 1888.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions*, 11 *Wall street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From Jan. 24th, to Feb. 14, 1888 (inclusive).

Alarms and Signals:—*Electric Call*, W. H. Cutting, 376,863, Jan. 24. *Electrical Auxiliary Signaling System*, G. F. Milliken and H. B. Lytle, 377,083. *Electric Annunciator*, J. W. Hoffman, 377,256, Jan. 31. *Electric Bell*, W. F. Stocker, 377,539. *Electro-Mechanical Signal Apparatus*, W. W. Le Grande, 377,626, Feb. 7. *Electric Bell*, J. P. Tirrell, 377,916, Feb. 14.

Clocks:—*Secondary Electric Clock*, W. B. Harvey, 377,895, Feb. 14.

Conductors, Insulators, Supports and Systems:—*Electrical Conductor*, T. Egleston, 376,818. *Underground Conduit for Electric Wires*, E. C. The Telephone Appeals.

AMOS E. DOLBEAR, *et. al.*, *Appellants*, *v.* THE AMERICAN BELL TELEPHONE CO.	U. S. C. C. Mass.
THE MOLECULAR TELEPHONE CO., *et. al.*, *Appellants*, *v.* THE AMERICAN BELL TELEPHONE CO., *et. al.*	U. S. C.C. S. D. N. Y.

[Cross Appeal in the Same Case.]

THE CLAY COMMERCIAL TELEPHONE CO., *et al.* *v.* THE AMERICAN BELL TELEPHONE CO., *et al.*	U. S. C. C. E. D. Pa.
THE PEOPLE'S TELEPHONE CO., *et al.*, *Appellants*, *v.* THE AMERICAN BELL TELEPHONE CO., *et al.*	U. S. C. C. S. D. N. Y.
THE OVERLAND TELEPHONE CO., *et al.*, *Appellants*, *v.* THE AMERICAN BELL TELEPHONE CO., *et al.*	U. S. C. C. S. D. N. Y.

WASHINGTON, D. C., March 19, 1888.

The CHIEF JUSTICE—I have been instructed by the Court to announce its judgment this morning in the six cases known as the telephone cases, and as the opinion is rather long, and my voice is weak and not under control, I have asked Judge Blatchford to read it.

Mr. JUSTICE BLATCHFORD—This opinion is in case No. 118, *Amos E. Dolbear* and other appellants, versus *The American Bell Telephone Co.*, an appeal from the Circuit Court of the United States for the District of Massachusetts.

In cases No. 361 and 362, which are cross-appeals from the Circuit Court of the United States for the Southern District of New York, one by the *Molecular Telephone Co.* and others, appellants, against *The American Bell Telephone Co.* and another, and a cross-appeal by *The American Bell Telephone Co.* and another, versus *The Molecular Telephone Co.* and others.

Another case is No. 709, *The Clay Commercial Telephone Co.* and others, appellants, versus *The American Bell Telephone Co.* and others; an appeal from the Circuit Court of the United States for the Eastern District of Pennsylvania.

Another is case No. 770. *The People's Telephone Co.* and others, appellants, against *The American Bell Telephone Co.* and others, an appeal from the Circuit Court of the United States for the Southern District of New York.

Another is case No. 771, *The Overland Telephone Co.* and others, appellants, against *The American Bell Telephone Co.* and others, an appeal from the Circuit Court of the United States for the Southern District of New York.

The opinion is written by the Chief Justice.

BELL'S CLAIM FOR THE ART.

The important question which meets us at the outset in each of these cases, is as to the scope of the fifth claim of Bell's patent of March 7, 1876, which is as follows:

> The method of and apparatus for transmitting vocal or other sounds telegraphically, as herein described, by causing electrical undulations similar in form to the vibrations of the air accompanying the said vocal or other sounds, substantially as set forth.

It is contended that this embraces the art of transferring to or impressing upon a current of electricity, the vibrations of air produced by the human voice in articulate speech, in such a way that the speech will be carried to and received by a listener at a distance on the line of the current. Articulate speech is not mentioned by name in the patent. The invention as described, consists in the employment of a vibratory or undulatory current of electricity, in contradistinction to a merely intermittent or pulsatory current, and of a method of, and apparatus for producing electrical undulations upon the line wire.

A pulsatory current is described as one caused by sudden or instantaneous changes of intensity, and an electrical undulation as the result of gradual changes of intensity, exactly analogous to the changes in the density of air occasioned by simple pendulous vibrations.

Among the uses to which this art may be put, is said to be the telegraphic transmission of noises or sounds of any kind; and it is also said that the undulatory current, when created in the way pointed out, will produce through the receiver at the receiving end of the line, a similar sound to that uttered into the transmitter at the transmitting end. One of the means of imparting the necessary vibrations to the transmitter to produce the undulations may be the human voice. Articulate speech is certainly included in this description, for it is an uttered sound produced by the human voice.

It is contended, however, that "vocal sounds" and "articulate speech" are not convertible terms, either in acoustics or in telegraphy. It is unnecessary to determine whether this is so or not. Articulate speech necessarily implies a sound produced by the human voice. As the patent, on its face, is for the art of changing the intensity of a continuous current of electricity by the undulations of the air caused by the sonorous vibrations, and speech can only be communicated by such vibrations, the transmission of speech in this way must be included in the art. The question is not whether vocal sounds and articulate speech are used synonomously as scientific terms, but whether articulate speech is one of the vocal or other sounds referred

to in this claim of the patent. We have no hesitation in saying that it is, and that if the patent can be sustained to the full extent of what is now contended for, it gives to Bell, and those who claim under him, the exclusive use of this art for that purpose until the expiration of the statutory term of his patented rights.

In this art, or what is the same thing under the patent law, this *process*, this *way* of transmitting speech, electricity, one of the forces of nature, is employed; but electricity left to itself will not do what is wanted. The art consists in so controlling the force as to make it accomplish the purpose.

It had long been believed that if the vibrations of air caused by the voice in speaking could be reproduced at a distance by means of electricity, the speech itself would be reproduced and understood. How to do it was the question. Bell discovered that it could be done by gradually changing the intensity of a continuous electrical current, so as to make it correspond exactly to the changes in the density of the air caused by the voice. This was his art. He then devised a way in which these changes of intensity could be made and speech actually transmitted. Thus his art was put in a condition for practical use. In doing this, both discovery and invention, in the popular sense of those terms, were involved; discovery in finding the art, and invention in devising means of making it useful; and for such discovery and such invention, the law has given the discoverer and inventor the right to a patent; as discoverer, for the useful art, process and method of doing the thing he has found, and as inventor, for the means he has devised to make the discovery one of actual value. Other inventors may compete with him for the ways of giving effect to the discovery, but the new art he has found will belong to him and those claiming under him, during the life of his patent. If another discovers a different art or method of doing the same thing, reduces it to practical use, and gets a patent for his discovery, the new discovery will be the property of the new discoverer, and thereafter the two will be permitted to operate, each in his own way, without interference by the other. The only question between them will be whether the second discovery is in fact different from the first.

A patent for the art does not necessarily involve a patent for the particular means employed for using it. Indeed, the mention of any means in the specification or descriptive portion of the patent, is only necessary to show that the art can be used; for it is only useful arts, arts which may be used to advantage, that can be made the subject of a patent. The language of the statute is:

> Any person who has invented or discovered any new or useful art, machine, manufacture or composition of matter may obtain a patent.

That is section 4886 of the Revised Statutes. It is an art, a process which is useful, and is as much the subject of a patent as a machine, manufacture or composition of matter. Of this there can be no doubt. It is abundantly supported by the authorities. *Corning* v. *Burden*, 15 How., 252-271. *Tilghman* v. *Proctor*, 12 How., 707-735. *Fermentation Company* v. *Maus*, 20 Fed. Rep., 725.

What Bell claims, is the art of creating changes of intensity in a continuous current of electricity exactly corresponding to the changes of density in the air caused by the vibrations which accompany vocal or other sounds, and of the use of the electric condition that is thus created for sending and receiving articulate speech telegraphically. For that, among other things, the patent of 1876 was, in our opinion, issued, and the point to be decided is, whether as such a patent it can be sustained.

In *O'Reilly* v. *Morse*, (15 How.) it was decided that a claim in broad terms for the use of the motive power of the electric or galvanic current for making intelligible characters, letters or sounds at any distance, although a new application of the power was made by Morse, was void, because it was a claim for a patent for an effect produced by the use of electro-magnetism, distinguished from the process or machinery necessary to produce it.

But a claim for making use of the motive power of magnetism when developed by the action of said current, substantially as set forth in the foregoing description, as a means of operating or governing the motion or machinery that is to impart signals in any desired manner for the purpose of producing telegraphic communication at any distance, was sustained. The effect of the decision was, therefore, that the use of magnetism as a motive power, without regard to the particular process with which it was connected in the patent, could not be claimed; but that its use in such a connection could.

In the present case the claim is not for the use of a current of electricity in its natural state, as it comes from the battery; but for putting a continuous current in a closed circuit into a certain specific condition suited to the transmission of vocal and other sounds, and using it in that condition for that purpose. So far as at present known, without this peculiar change in its condition, it will not serve as a medium for the transmission of speech, but with the change it will. Bell was the first to discover this fact and how to put such a current into such a condition. What he claims is its use in that condition for that purpose, just as Morse claimed his current in his condition for his purpose. But we see nothing in the Morse case to defeat Bell's claim. On the contrary it is in all respects sustained by that authority. It may be that electricity cannot be used at all for the transmission of speech except in the way Bell has discovered it, and that, therefore, practically his patent gives him its exclusive use for this purpose. But that does not make his claim one for the use of electricity as distinguished from the particular process with which it is connected in his patent. It will, if it is true, show more clearly the great importance of his discovery, but it will not invalidate his patent.

SUFFICIENCY OF THE SPECIFICATION.

But it is insisted that his claim cannot be sustained, because when the patent was issued Bell had not, in fact, completed his discovery. While it is conceded that he was acting on the right principle and had adopted the true theory, it is claimed that his discovery lacked that practical development which was necessary to make it patentable. In the language of counsel "there was still work to be done, work calling for the exercise of the utmost ingenuity and calling for the very highest degree of practical invention."

It is quite true that when Bell applied for his patent he had never actually transmitted telegraphically spoken words so that they could be distinctly heard and understood by the listener at the receiving end of his line, but in his specification he did describe accurately and with admirable clearness, his process, that is to say the exact electrical condition that must be created to accomplish the purpose. He also described with sufficient precision to enable one skilled in such matters to make it, a form of apparatus, which if used in the way pointed out, would produce the required effect, receive the words and carry them to and deliver them at the appointed place. The particular instrument which he had, and which he used in his experiments did not under the circumstances in which it was tried, reproduce the words spoken so that they could be clearly understood; but the proof is abundant and of the most convincing character that other instruments carefully constructed and made in exact accordance with the specifications without any additions whatever have operated and will operate successfully. A good mechanic of proper skill in matters of the kind can take the patent and by following the specification strictly, can, without more, construct an apparatus which when used in the way pointed out, will do all that it is claimed the method or process will do.

Some witnesses have testified that they were unable to

do it, but this shows that they, with the particular apparatus they had and the skill they employed in its use, were not successful; not that others with another apparatus perhaps more carefully constructed or more skilfully contrived would necessarily fail. As was said in *Loom Company* v. *Higgins*, when the question is whether a thing can be done or not, it is always easy to find persons to show how not to do it. If one succeeds, that is enough, no matter how many others fail. Opposite results will show that in the one case the apparatus used was properly made, and carefully adjusted with a knowledge of what was required, and skillfully used; and that in the other it was not. The law does not require that a discoverer or inventor, in order to get a patent for a process, must have succeeded in bringing the art to the highest degree of perfection. It is enough if he describes the method with sufficient clearness and precision to enable those skilled in the matter to understand exactly what the process is, and if he points out some practicable way of putting it in operation. This Bell did.

He described clearly and distinctly his process of transmitting speech telegraphically by creating changes in the intensity of a continuous current or flow of electricity in a closed circuit, exactly analogous to changes of density in the air occasioned by the undulatory motion given to it by the human voice in speaking. He then pointed out two ways in which this might be done, one, by the vibration or motion of bodies capable of inductive action or by the vibration of the conducting wire itself in the neighborhood of such bodies; and the other by alternately increasing and diminishing the resistance of the circuit or by alternately increasing and diminishing the power of the battery. He then states that he prefers to employ for his purpose an electro-magnet having a coil on one of its legs, and he describes the construction of the particular apparatus, shown in the patent as figure 7, in which the electro-magnet or magneto method was employed. This was the apparatus which he himself used without entirely satisfactory results, but which Professor Cross, Mr. Watson, Doctor Blake, Mr. Pope and others, testify has done and will do what was claimed for it, transmit speech successfully, but not as well indeed as another constructed upon the principle of the microphone or variable resistance method.

THE PATENT NOT LIMITED TO SPECIFIC APPARATUS.

An effort was made in the argument to confine the patent to the magneto instrument, and such modes of creating electrical undulations as could be produced by this form of apparatus, the position being that such an apparatus necessarily employed a closed circuit incapable of being opened, and a continuous current incapable of being intermittent. But this argument ignores the fact that the claim is, first, for the process and, second, for the apparatus. It is to be read, as *first*, a claim for the method of transmitting vocal or other sounds telegraphically, as herein described, by causing electrical undulations similar in form to the vibrations of air accompanying the vocal or other sounds substantially as set forth, and, *second*, for an apparatus for transmitting vocal or other sounds telegraphically as herein described, by causing electrical undulations, substantially as set forth.

The *method* "as herein described" is to cause gradual changes in the intensity of the electrical current used as the medium of transmission, which shall be exactly analogous to the changes in the density of the air occasioned by the peculiarities in the shapes of the undulations produced in speech, in the manner substantially as set forth; that is to say, by the vibration or motion of bodies capable of inductive action, or by the vibration of the conducting wire itself in the neighborhood of such bodies, which is the magneto method; or by alternately increasing and diminishing the resistance of the circuit, or by alternately increasing and diminishing the power of the battery, which is the variable resistance method. This is the process which has been patented, and it may be operated in either of the ways specified. The circuit must be kept closed to be used successfully; but this does not necessarily imply that it must be so constructed or so operated upon as to be incapable of being opened. If opened, it will fail to act for the time being, and the process will be interrupted; but there is nothing in the patent which requires it to be operated by instruments which are incapable of make and break. The *apparatus*, "as herein described," which is included in the claim, is undoubtedly one in which the electro-magnet is employed, constructed substantially as set forth in the specification. The one acting on the variable resistance mode is not described, further than to say that the vibration of the conducting wire in mercury or other liquid included in the circuit occasions undulations in the current; and no very specific directions are given as to the manner in which it must be constructed. The patent is both for the magneto and variable resistance *methods* and particularly for the magneto *apparatus* which is described or its equivalent. There is no patent for any variable resistance *apparatus*.

It is undoubtedly true that when Bell got his patent he thought the magneto method was the best. Indeed, he said in express terms he preferred it. But that does not exclude the use of the other, if it turns out to be the most desirable way of using the process under any circumstances. Both forms of apparatus operate on a closed circuit by a gradual change of intensity, and not by alternately making and breaking the circuit or by sudden and instantaneous changes, and they each require to be so adjusted as to prevent interruptions. If they break, it is a fault, and the process stops until the connection is restored.

It is again said that the claim, if given its broad construction, is virtually a claim for speech transmission by transmitting it, or in other words, for such doing of the thing as is provable by doing it. It is true Bell transmits speech by transmitting it; and that long before he did so it was conceived by scientists that it could be done by means of electricity, if the requisite electrical effect could be produced. Precisely how that subtle force operates under Bell's treatment, or what form it takes no one can tell. All we know is, that he found that by changing the intensity of a continuous current so as to make it correspond exactly to the changes in density of the air caused by sonorous vibrations, vocal and other sounds could be transmitted and heard at a distance. This is the thing to be done. Bell discovered the way of doing it. He uses electricity as the medium for that purpose just as air is used within speaking distance. In effect, he prolongs the air vibrations by the use of electricity. No one before him had found out how to use electricity with the same effect. To use it with success it must be put in a certain condition. What that condition was he was the first to discover, and with his discovery he astonished the scientific world. Professor Henry, one of the most eminent scientists of the present century, spoke of it as the greatest marvel hitherto achieved by the telegraph. The thing done by Bell was the transmitting of audible speech through long telegraph lines. Sir William Thomson on returning to his home in England in August or September, 1876, after seeing at the Centennial Exhibition in Philadelphia what Bell had done and could do by his process, spoke in this way of it to his countrymen:

> Who can but admire the hardihood of invention, which devised such a slight means to realize the mathematical conception, that if electricity is to convey all the delicacies of quality which distinguish articulate speech, the strength of the current must vary continuously as nearly as may be in simple proportion to the velocity of the particle of air engaged in constituting the sound.

Surely a patent for such a discovery is not to be confined to the mere means he improvised to prove the reality of his conception.

BELL'S METHOD NOT IN REIS' APPARATUS.

We come now to consider the alleged anticipation of Philipp Reis; and here it is to be always kept in mind that the question is not whether the *apparatus*, devised by Reis to give effect to his theory, can be made with our present knowledge, to transmit speech; but whether Reis had in his time found out a way of using it successfully for that purpose, not as to the character of the apparatus, but as to the mode of treating the current of electricity on which the apparatus is to act, so as to make that current a medium for receiving vibrations of air created by the human voice in articulate speech at one place, and in effect delivering them at the ear of the listener in another place. Bell's patent is not alone for the particular apparatus that he describes, but for the process that apparatus was designed to put into use. His patent would be just as good if he had actually used the Reis apparatus in developing the process for which it was granted. That Reis knew what had to be accomplished in order to transmit speech by electricity is very apparent, for in his first paper he said:

> Since it is possible to produce anywhere or in any manner vibrations whose curves shall be the same as those of any given tone or combination of tones, we shall receive the same impression as that tone or combination of tones would have produced on us.

Bourseul also knew before Reis that this was the case, for in a communication published in the Paris journals in 1854 he said:

> When you reproduce precisely these vibrations, to wit, the vibrations made by the human voice in uttering syllables, you will reproduce precisely those syllables.

Reis discovered how to reproduce musical tones, but he did no more. He could sing through his telephone, but he could not talk. From the beginning to the end he has conceded this. In his first paper he said:

> Hitherto it has not been possible to produce the tones of human speech with a distinctness sufficient for every one. The consonants are for the most part reproduced pretty distinctly, but the vowels as yet not in an equal degree. The cause of this I will attempt to explain.

And again:

> I have succeeded in constructing an apparatus with which I am enabled to reproduce the tones of various instruments, and even to a certain extent the human voice.

None of the many writers whose papers are found in the records, claim more than this for Reis or his discovery. Although his first paper was published in 1861, Bell did not appear as a worker in the same field of scientific research until nearly 15 years afterwards. No advance had been made by the use of what Reis had contrived, nor by the use of his method, towards the great end to be accomplished. He caused his instrument to be put in the market for sale, and both he and those he employed for that purpose, took occasion to call attention to the instruments by their prospectus, catalogues and otherwise, describing what they were and what they would do. In his own prospectus, which was published in 1863 and attached to the apparatus, he said:

> Every apparatus consists of two parts, the telephone proper and the receiver. These two parts are placed at such distance from each other that the singing or toning of a musical instrument can be heard in no other way from one station to the other except through the apparatus.
>
> Both parts are connected with each other and with the battery B, like common telegraphs . . . The galvanic current goes . . . . through the copper strip to the platinum leaf on the middle of the membrane, then through the foot of the angle to the screw *b*, in whose hollow a small drop of mercury is placed . .
>
> If now sufficiently strong tones are produced in front of the sound-opening S, through the vibrations of the same, the membrane and the angular-shaped little hammer lying upon it are set in vibration; *the circuit is alternately opened and closed at every full vibration* and hereby are produced in the iron rod of the spiral at station C the same number of vibrations, and those are perceived there as tone or tone combinations.
>
> Besides the human voice there can be produced (according to my experience) just as well the tone of good organ pipes from F—*c* and those of the piano.

Albert, the mechanician employed to make the instruments, in his catalogue published in 1866, enumerates among the things he has for sale "the telephone of Reis for reproducing tones by electricity;" and in a work on electricity by Ferguson, published in London and Edinburgh, in 1867, it is said in speaking of the telephone:

> This is an instrument for telegraphing notes of the same pitch. Any noise producing a single vibration of the air, when repeated regularly a certain number of times a second, not less than 32, produces, as is well known, a musical sound. A person when singing any note causes the air to vibrate so many times per second, the number varying with the pitch of the note he sings. The higher the note the greater the number of vibrations. If we then by any means can get these notes to break a closed circuit, a note sung at one station can be reproduced, at least as far as pitch is concerned, at another. The Reis telephone, invented in 1861, accomplishes this in the following way.

It is needless to quote further from the evidence on this branch of the case. It is not contended that Reis ever succeeded in practically transmitting speech, but only that his instrument was capable of it if he had known how. He did not know how. All his experiments in that direction were failures. With the help of Bell's later discoveries in 1875, we now know why he failed.

As early as 1854 Bourseul, in his communication which has already been referred to, had said substantially that if the vibrations of air produced by the human voice in articulate speech could be reproduced by means of electricity at a distance, the speech itself would be reproduced and heard there. As a means of stimulating inquiry to that end, he called attention to the principle on which the electric telegraph was based, and suggested the application of that principle for such a purpose. He said:

> The electric telegraph is based on the following principle: An electric current passing through a metallic wire circulates through a coil around a piece of soft iron, which it converts into a magnet. The moment the current stops, this piece of iron ceases to be a magnet. This magnet takes the name of electro-magnet.
>
> This magnet, the electro-magnet, can thus alternately attract or let go a movable plate, which by its movements back and forth, produces the conventional signals used in telegraphy.

Then, after referring to the mode in which speech is transmitted by the vibrations of the air, he said:

> Suppose a man speaks near a movable disc sufficiently flexible to lose none of the vibrations of the voice, and that this disc alternately makes and breaks the connection with the battery; and you may have at a distance another disc which may simultaneously execute the same vibrations.

That Reis was working all this time, from the beginning to the end of his experiments, upon the principle of the telegraph as thus suggested by Bourseul, is abundantly proved. In his first paper, after describing his cubical block apparatus, he said:

> If now tones or a combination of tones are produced in the neighborhood of the blocks, so that sufficiently powerful waves enter the opening *a*, then these sounds cause the membrane *b* to vibrate. At the first condensation the hammer-like wire *d* is pushed back; at the rarefaction it cannot follow the retreating membrane, *and the current traversing the strip remains broken*, until the membrane forced by a new condensation presses the strip (proceeding from *p*) against *d*. In this way *each sound causes a breaking and closing of the current.*

Such was the beginning and it was maintained persistently to the end, as well by Reis as by those who availed themselves of what he was doing. To this the Reis-Legat apparatus forms no exception, for in the paper describing it, Legat says:—

> The operation of the apparatus described is as follows:
>
> When at rest the galvanic circuit is closed, when the air, which is in the tube *a b* of the apparatus, Fig. 4 A, is alternately condensed and rarified by speaking into it (or by singing or introducing the tones of an instrument), a movement of a membrane closing the smaller opening of the tube is produced, corresponding to such condensation or rarefaction. The lever *c d* follows the movements of the membrane and opens and closes the galvanic circuit at *d g*, so that at each condensation of the air

in the tube the circuit is opened, and at each rarefaction the circuit is closed.

In consequence of this operation, the electro-magnet of the apparatus, Fig. 4 B, in accordance with the condensations and rarefactions of the column of air in the tube *a b*, Fig. 4 B, is correspondingly demagnatized and magnetized, and the armature of the magnet is set into vibrations like those of the membrane in the transmitting apparatus.

We have not had our attention called to a single item of evidence which tends in any way to show that Reis, or any one who wrote about him, had in his mind anything else than that the intermittent current caused by the opening and closing of the circuit could be used to do what was wanted. No one seems to have thought that there could be any other way. All recognized the fact that the minor differences in the original vibrations had not been satisfactorily reproduced, but they attributed it to the imperfect mechanism of the apparatus used, rather than to any fault in the principle on which the operation was made to depend.

It was left for Bell to discover that the failure was due not to workmanship, but to the principle which was adopted as the basis of what was to be done. He found that what he called the intermittent current, one caused by alternately opening and closing the circuit, could not be made, under any circumstances, to reproduce the delicate forms of the air vibrations caused by the human voice in articulate speech; but that the true way was to operate on an unbroken current, by increasing and diminishing its intensity. This he called a vibratory or undulatory current, not because the current was supposed to actually take that form, but because that language expressed with sufficient accuracy his idea of a current which was subjected to gradual changes of intensity, exactly analogous to the changes of density in the air occasioned by its vibrations. Such was his discovery, and it was new. Reis never thought of it and he failed to transmit speech telegraphically. Bell did, and he succeeded. Under such circumstances it is impossible to hold that what Reis did was an anticipation of the discoveries of Bell. To follow Reis is to fail, but to follow Bell is to succeed. The difference between the two is just the difference between failure and success. If Reis had kept on he might have found out the way to succeed; but he stopped and failed. Bell took up the work and carried it on to a successful issue.

OTHER ALLEGED ANTICIPATIONS OF BELL'S METHOD.

As to what is shown to have been written and done by Dr. Van der Weyde, it is only necessary to say that he copied Reis, and it was not until after Bell's success that he found out how to use a Reis instrument so as to make it transmit speech. Bell taught him what to do to accomplish that purpose.

As to James W. McDonough, we presume it will not be claimed that he is entitled to more than he asked for in his application for a patent, filed in the Patent Office, April 10th, 1876. There a circuit-breaker so adjusted as to break the connection by the vibration of the membrane is made one of the elements of his invention. The Patent Office was clearly right in holding him to have been anticipated by Reis.

The patents of Cromwell Fleetwood Varley, of London, England, one dated June 2d, 1868, and the other October 8th, 1870, were for improvements in the electric telegraph. The objects of the invention covered by the first are to cut off the disturbance arising from earth currents, and to obtain a high speed of signaling in long circuits; and the object of the second was the increase of the transmitting power by enabling more than one operator on a single wire to send more than one message to independent stations. In the specification it is said:

By my invention I superpose upon the currents used for working the ordinary telegraphs rapid undulations or waves which do not practically alter the mechanical or chemical power of the ordinary signal currents, and by new apparatus, hereinafter described, these undulations are made to produce distinct and independent audible or other signals so long as these undulations are produced, whether ordinary signal currents be flowing or not.

In short, there is nothing in any part of the specification to indicate that the patentee had in his mind undulations resulting from gradual changes of intensity exactly analogous to the changes in the density of air occasioned by simple pendulous vibrations, which was Bell's discovery, and on which his art rests. His purpose was to superpose, that is to say, to place upon the ordinary current, another, which by the action of the make and break principle of the telegraph, would do the work he wanted.

ALLEGED ANTICIPATION BY DANIEL DRAWBAUGH.

Another alleged anticipation is that of Daniel Drawbaugh. Bell got his patent March 7, 1876, and the fortunate accident which led to his discovery occurred June 2d, 1875. Active litigation to enforce the patent rights was begun by his company on the 12th of September, 1878, with a suit in the Circuit Court of the United States for the District of Massachusetts, against Peter A. Dowd. This suit was defended by the *Western Union Telegraph Co.*, and vigorously contested. The answer was filed November 4, 1878, setting up alleged anticipation by Gray, Edison, Dolbear and others. The record fills 1,200 printed pages; but before a decision was reached the case was compromised, and a decree entered by consent. The litigation ended some time in the latter part of the year 1879. The last deposition was taken on the 19th of September in that year.

The next contested suit was brought in the same court, on the 28th of July, 1880, against *Albert Spencer* and others. An answer was filed in this case, September 6, 1880, and depositions afterwards taken, some of those in the Dowd suit being used in this by stipulation. On the 27th of June, 1881, a decision was announced by Judge LOWELL, sustaining the patent, upon which a decree was entered.

On the 14th of November, 1879, Mr. A. G. Tisdel filed in the Patent Office an application for a patent for a new and useful improvement in speaking telephones. On the 18th of November, 1879, Frank A. Klemm also filed an application for a patent, for a new and useful improvement in telephone transmitters. These inventions were transferred by assignment to Ernest Marks and Frank A. Klemm, of New York city, —— Levy, of Cincinnati, and Simon Wolf, of Washington. On the 6th of March, 1880, these parties entered into a mutual agreement, to the effect that each and all of their interests in said improvements and inventions, and the letters patent to be issued therefor, should be merged and consolidated as the common stock in a corporate body under the laws either of the State of Ohio or New York, or the general laws of the United States, relating to the formation of corporations in the District of Columbia, or in such other States and Territories as might be found necessary hereafter. This agreement was recorded in the Patent Office March 10, 1880.

On the 6th of May, 1880, Edgar W. Chellis, a merchant of Harrisburg, Pennsylvania, H. W. Jacobs, a lawyer of the same place, and Lysander Hill, a lawyer then residing in Washington, in the District of Columbia, made an arrangement with Daniel Drawbaugh, by which they were to become jointly interested with him in his alleged telephone inventions, each to have a quarter interest. Nothing was paid for this, but each of the parties was to have one quarter of anything that should be realized from the enterprise. On the 24th of May, 1880, Simon Wolf, one of the parties interested in the Klemm and Tisdel inventions, visited Harrisburg on business with Chellis in reference to telephone matters. On the 18th of May, six days before this visit, a patent was issued to Wolf and his associates upon the invention of Tisdel. While Wolf was in Harrisburg, negotiations were begun by Chellis for the transfer

of the Drawbaugh inventions, and these negotiations resulted in a conditional contract on the 22d of June, by reason of which Chellis, Jacobs, Hill and Drawbaugh went to Washington. There on the 21st of July, 1880, Drawbaugh, claiming to have invented "new and useful improvements in the transmission of vocal speech, and the apparatus to be used for those purposes, for which I am about to make application for letters patent of the United States" assigned to Klemm, Marx, Wolf and Levy, the full and exclusive right to the said inventions as fully set forth and described "in the specifications prepared and executed by me, dated 21st July, 1880, preparatory to obtaining Letters Patent of the United States therefor." He at the same time, and by the same instrument, authorized and requested the Commissioner of Patents to issue the patent to his assignees, each as assignee of one-quarter part. The specification referred to in the assignment has not been put in evidence in any of the cases. In the course of taking the testimony it was called for by the Bell company, but the counsel for the opposite party declined to produce either the original or a copy from the Patent Office. The assignment was recorded in the Patent Office July 22nd, 1880, and in the official Digest of Assignments the following notice appears:

About to make application. Specification dated July 21st, 1880.

On the morning of July 22nd, 1880, the following article appeared in the *Cincinnati Commercial*, a newspaper printed at Cincinnati, Ohio:

TELEPHONE COMBINATION.

Special to the *Cincinnati Commercial*.

WASHINGTON, D. C., July 21.

An application for a patent was filed to-day, that in consequence of its vastness of interest, as well as wealth of prospect, renders it a subject of national interest. A company of leading business men has been formed, that has bought up all the telephone patents antedating those now in use, and known as the Bell, Gray, and Edison patents. The company is composed of leading business men from all parts of the country, Cincinnati being largely represented and interested. The cash capital of the company is $5,000,000, with headquarters in New York, and in about 60 days they will open up the telephone, which will certainly result in the driving out of all telephones in the market, save the ones they hold, or else in compelling the Gray, Bell and Edison lines to pay the new company a munificent royalty. It appears from the testimony now on file and in the possession of the new company, which is conclusive and exhaustive, that the inventor of the telephone is a poor mechanic, living near Harrisburg, Pa., named Daniel Drawbaugh. Owing to his poverty, he was unable to push his patent on the market. The new company have secured and are sole possessors of this invention, antedating those now in use. They are also owners of four patents for telephones issued to Mr. Klemm, of New York. A large number of capitalists were here to-day to see the filing of the application, and they assert, with a positiveness that is almost convincing, that it will not be long till they have entire charge of the telephones, not only in this country but in the world, and that they will be able to establish lines by which messages can be transmitted for almost a song.

Mr. Lipman Levy, of the law firm of Moulton, Johnson & Levy, of Cincinnati, was here to-day in the interest of the Cincinnati parties, who, as already stated, are among the most prominent financial men of our city.

Afterwards, on the 23rd of August, 1880, the following appeared in the *Journal of Commerce*, a newspaper printed in the City of New York:

A New Telephone Company.—A company has recently been formed in this city with a capital of $5,000,000 for the purpose of manufacturing telephones. The company is to be known as the People's Telephone Company, and a number of leading capitalists in this city and Cincinnati are interested in it. The telephones are to be manufactured under the patents of Frank A. Klemm and Abner G. Tisdel, and the application for patents of Daniel Drawbaugh, of Eberly's Mills, Cumberland county, Pa., filed July 21st, 1880. It is claimed by those interested in the new enterprise that Drawbaugh is really the inventor of the telephone, and had completed one years before Professor Bell or any one else had manufactured one. He was, however, in very humble circumstances, and his neighbors who knew of his experiments looked upon him as a harmless lunatic. He continued improving his original telephone, and it is claimed that the one which the new company proposes to furnish is superior to any now in use. The company has fitted up a factory in Brooklyn, and in three months will be prepared to supply 1,000 of the new telephones. As soon as operations are actively commenced, it is expected that legal proceedings will be begun against the new company by the Gold and Stock Telegraph Company, which holds most of the existing patents, and a long and interesting legal fight is anticipated.

On the 30th of August, 1880, the People's Telephone Co. was incorporated under the general laws of New York, with an authorized capital stock of $5,000,000, for manufacturing, constructing, owning, furnishing, letting and selling telephones and the apparatus used therewith under the inventions and patents of Abner G. Tisdel, Frank A. Klemm, Daniel Drawbaugh, and other inventions and patents which may hereafter be assigned to that company. On the 4th of September, 1880, Klemm, Loth, Marx and Wolf, in consideration of $4,999,550, represented by 99,991 shares of stock, assigned and transferred to that company all their interests in the Klemm, Tisdel and Drawbaugh inventions, those of Drawbaugh being described as "inventions in telephones made by Daniel Drawbaugh, of Eberly's Mills, Cumberland county, Pennsylvania, for which applications for patents were made on or about the 21st of July, 1880, and which were assigned to us on the 31st of July, 1880, as more particularly appears in the deed of assignment, recorded in the United States Patent Office." For the assignment from Drawbaugh to Klemm, Marx, Loth and Wolf, $20,000 was paid in money to Chellis, Jacobs and Hill, and they were allowed to have a certain amount of the stock of the proposed corporation then formed. What amount they actually got, Chellis, who was sworn as a witness in the case, declined to state, but he admitted it was large.

At this time and in this way, the attention of the general public was called, for the first time, to the fact that Drawbaugh claimed to have anticipated Bell in the discovery of the telephone. Bell's success had been proclaimed more than four years before, at the Centennial Exhibition in Philadelphia. In the meantime inventions in aid of his discovery had been multiplied. According to the testimony of Park Benjamin, more than 100 patents had then been issued and indexed under the word "telephone," and numerous interferences had been declared and considered by the Patent Office. Gray, Edison, Dolbear and others, had either claimed for themselves, or others had claimed for them, priority of invention and discovery, and Bell had thus far been sustained as against them all. Blake had perfected his microphone apparatus, and Bell's patent had become a great commercial success. The People's company either began, or threatened to begin operations under its charter, and on the 20th of October, 1880, the Bell company brought suit against it in the Circuit Court of the United States for the Southern District of New York, to prevent any infringement of the Bell patent. In the bill it was alleged that—

telephone exchanges now exist in more than 275 towns and cities of the United States, and in every state thereof, and exist in substantially every city having more than 15,000 inhabitants, and in many smaller places. . . . . . That there are now in use more than 100,000 electric speaking telephones, licensed by and paying royalty to the Bell company; that the owners of the Bell patents, and those who now are or heretofore have been licensees of them, have devoted great time and attention and large sums of money to the development of the telephone and the introduction thereof into extensive use, and to the proper construction of the most suitable telephone lines and systems, and telephonic appliances, and have constructed many thousand miles of telephone lines for use with telephones owned by the Bell company and licensed by it for such use; and nothing which the defendants, or F. A. Klemm, A. G. Tisdel or Daniel Drawbaugh have done, has contributed in any substantial way to the development of the telephone or the introduction thereof into use.

The bill then avers that Klemm, Marx, Levy and Wolf, having become the owners of these inventions, and having heard that Daniel Drawbaugh claimed that—

he had made some experiments relating to electric speaking

telephones (which experiments, if made, were incomplete, imperfect, unfruitful and long before abandoned), entered into an arrangement with him to set up and claim that he was the first inventor of the electric speaking telephone, and to make application for a patent therefor; and that thereafter alleging and pretending that said Drawbaugh was the original and first inventor of the electric speaking telephone, and that electric speaking telephones had not before such application been in public use or on sale for more than two years with the knowledge and consent of Drawbaugh, did on or about the 21st of July, 1880, induce him to make and cause to be filed in the Patent Office of the United States an application for a patent, to issue to them as the assignees of the said Drawbaugh as the first and original inventor of the electric speaking telephone.

It was then further alleged that if Drawbaugh had ever made his pretended inventions, they had not been, by him or any one claiming under him, introduced into public use, and "that knowledge thereof has been witheld from your orators and the public, except so far as they have been disclosed within the three months last past by certain newspaper publications."

To this bill the People's company filed an answer in December 1880 or January 1881. The record does not show the precise date. In this answer it was said that Drawbaugh was the original and first inventor and discoverer of the art of communicating articulate speech between distant places by voltaic and magneto-electricity, and that long prior to the alleged invention by Bell, Gray and Edison, he then and now residing at Eberly's Mills constructed an apparatus which was a practical working electric speaking telephone, at said Eberly's Mills, and exhibited the same in successful operation to a great number of other persons residing in his vicinity and elsewhere; and that his telephones as then constructed and operated contained all the material and substantial parts and inventions patented in the patents of Bell, and also other important and valuable inventions in electric and magneto telephones, and were actually used for transmitting articulate vocal sounds and speech between distant points by means of electric currents; that he had the original instrument which he used and had exhibited to many others long prior to the said alleged inventions of Bell or either of them; that they are still in existence and capable of successful and practical use, and are identified by a large number of persons who personally witnessed their practical operation and use in the years 1870, 1871, 1872, 1873 and 1874 and several years prior and subsequent thereto; that certainly more than fifty and probably not less than one hundred persons, or even more were cognizant of said Drawbaugh's invention and use of said telephone, and of his claiming to be the original and first inventor thereof prior to the alleged inventions of said Bell or either of them; that said Drawbaugh for more than ten years prior to the year 1880 was miserably poor, in debt, with a large and helpless family dependent upon his daily labor, and was from that cause alone utterly unable to patent his invention or caveat it, or manufacture and introduce it on the market; that said Drawbaugh never abandoned the said invention nor acknowledged the claim of any other person or persons thereto, but always persisted in his claims and intended to patent it as soon as he could procure the necessary means therefor. That said Drawbaugh never acquiesced in the public use of said Bell, Gray, Edison, Blake or other telephones, nor in the claims of the alleged inventors nor gave his consent to such use.

It is then said that Drawbaugh, after finding by experiment that his invention was capable of successful working, conceived that its range and capacity for usefulness to the public might be greatly enlarged, and that many improvements of great value might be made and added to it, which without departing from its principle, might increase its value to himself and to the public; and therefore set himself at work to discover and invent such improvements; that he discovered and invented some such improvements prior to any alleged invention by the said Bell; and then, notwithstanding his embarrassed and impoverished pecuniary condition, and his utter want of proper mechanical tools, materials and appliances to conduct such work, he labored with all reasonable diligence to perfect and adapt his said improvements, and did finally, in due exercise of such reasonable diligence, perfect and adapt the same; and that, in so far as the said Bell has incorporated such improvements in his said two patents, or either of them, he, the said Bell, has surreptitiously and unjustly obtained a patent or patents for that which was in fact first invented by said Drawbaugh, who was using reasonable diligence in perfecting and adapting the same; and therefore, the patent or patents of the said Bell therefor is, or are, invalid and void.

It is then said that—

the defendants in good faith, and relying upon his legal rights, caused application to be made and filed in the Patent Office for the invention of the said Daniel Drawbaugh, with the intention of procuring interference proceedings to be instituted in accordance with the statute, against the patents of said Bell, and the pending applications of said Gray, Edison and others, in order that said Drawbaugh might be adjudged by the Commissioner of Patents to be the original and first inventor of the electric speaking telephone, and might be adjudged entitled to receive a patent or patents therefor.

The People's company began taking depositions on the 19th of April, 1881, but Drawbaugh himself did not appear as a witness until December 7th, 1881. After that time others were examined, and when the proofs were closed, between three and four hundred witnesses had been produced whose testimony was taken and put into the record to establish the priority of Drawbaugh's invention. This testimony, as is now claimed, shows the story of that invention to have been as follows:

Early conception and experiments with a continuous current, 1862 and 1866 and 1867.
Tea-cup transmitter and receiver, 1866 and 1867.
Tumbler, tea-cup and mustard can, F and D, 1867 and 1869.
Improvement on B, namely, C, 1869 and 1870.
Further improvements on C and the more perfect magneto-instrument I, 1870 and 1871.
Mouth-piece changed to centre and adjusting-screw inserted (exhibit A), 1874.
D and E, perfectly adjusted and finished magneto-instruments, January and February, 1875.
L, M, G and O, February 1875 to August, 1876.
H, August, 1876.
J, N and P, 1878.

This statement of the Drawbaugh claim we have quoted from the brief of counsel appearing in his behalf, and his success in the litigation has been based, as we understand it, both in the answer and in the argument, on the truth or falsehood of what is thus set forth.

The letters F and D, &c., in the statement, refer to exhibits in the case, being certain instruments claimed to have been made and used by Drawbaugh in the progress of his work, and preserved until now. The original teacup instrument was not produced, but Drawbaugh gave in his deposition what he said was a drawing showing how it had been constructed. F, B, C, D, I and A, were neither of them in a condition for use when they were put in evidence, and none of the witnesses except Drawbaugh could tell how they were originally constructed, or what the process was by which sound was transmitted when they were used. All that any of the witnesses could say on that subject was that they had used one or more of the different instruments at Drawbaugh's shop, and heard sounds and sometimes words spoken to them, and that Drawbaugh told them the sound was carried on the wire by electricity. There was nothing whatever produced in print or in writing on the subject, nor even a memorandum or drawing of any kind, and there is nothing in the testimony to show that Drawbaugh ever told any one how his earlier instruments were made, or what his process was, until he was called as a witness in December, 1881, and explained it in his testimony. This was nearly twenty years, according to the present claim, after he had begun his experiments, nearly seven years after he had made and used D and G,

perfectly adjusted and finished magneto instruments, more than five years after L, M, G, O and H, had been constructed and connected in his shop, if his story is true. It was also nearly six years after the date of Bell's patent, more than five years after the success of his discovery had been proclaimed at the Centennial Exhibition in Philadelphia, four years after his invention had gone into public use, three years after it had become an established success, and two years after he had brought the first suit for the establishment of his right against Dowd, who represented the Western Union Telegraph Company, to a successful termination.

THE CONDUCT OF DRAWBAUGH CONSIDERED.

Under these circumstances it becomes important to consider the conduct of Drawbaugh in reference to his alleged invention during his twenty years of eventful history, as connected with the discovery and use of the telephone. If his present claim is true his experiments began almost as far back as those of Reis, and he had in his shop at Eberly's Mills, within three miles of Harrisburg, telephones that were substantially perfect months before Bell (on the 2nd of June) 1875. got the clue to his subsequent discovery. It is conceded that D and E, claimed to have been made in February, 1875, are substantially as good magneto instruments as any Bell had used before December, 1881 ; and L, M, G, O and H, all of which were constructed, it is claimed, between February, 1875, and August, 1876, are as good, or nearly as good microphones as those of Blake, which were not invented until 1878. This is the theory of Drawbaugh's defense, as set forth in the answer and in the argument, and by it his case must stand or fall.

The claim is that the discovery of the process was complete, and that perfect telephones had been made and were in a condition for actual use a year and more before Bell got his patent.

Drawbaugh was, when he gave his deposition, 54 years of age, and had lived all his life at or near Eberly's Mills, a small village near Harrisburg. He was a skillful and ingenious mechanic, and if he made D and E, and the instruments which came after them at the time it is said he did, he had good tools and good material in 1875 and 1876, and was capable of doing the best of work. He was also somewhat of an inventor, and had some knowledge of electricity. According to the testimony he was an enthusiast on the subject of his talking machine, and showed it freely to his neighbors and people from the country, whenever they visited his shop.

The Centennial Exhibition was opened in Philadelphia, in May, 1876. Drawbaugh visited it on the 17th of October, 1876, remaining four or five days. Before he went he had heard, as he says, that some one besides himself had invented a speaking telephone, which he had the impression was on exhibition there. If what he now claims is true, he had then on hand in his shop, exhibits D, E, L, M, G, O, and H, all of them good instruments of their kind and capable of transmitting speech, and some of them but just finished. Bell's apparatus had been exhibited to the Board of Judges in June before, and had attracted marked attention. The matter was much discussed in the public press, and yet it never seems to have occurred to Drawbaugh to take any of his telephones with him when he went, although they were small in size, and some or all of them could have been carried without serious inconvenience. When giving his testimony he was examined in chief as to that visit, and this is what he said on the subject of telephones :

Q. Did you attend the Centennial Exhibition at Philadelphia in 1876? *A*. Yes sir, I did.

Q. Can you give the date on which you went there? *A*. I can by reference to a book. It was October, 1876. The 17th was a day on which I dated a letter from Philadelphia when I was there on that visit.

Q. How long did you visit there last? *A*. About four or five days, to the best of my recollection.

Q. Who went with you on that visit? *A*. Mr. George Leonard.

Q. Was that the only visit to the Centennial Exhibition that you made? *A*. Yes sir ; it was.

Q. At the time that you went there, or before that time, had you heard that somebody else besides yourself had invented a speaking telephone or a telephone? *A*. Yes, sir ; some time before that. I don't remember how long, but not a great while.

Q. When you went there, did you suppose it would be on exhibition there? *A*. I don't remember whether I had heard that it was on exhibition or not, but I got the impression some way that it was on exhibition.

Q. While you were there at the Centennial did you see any telephones or make an effort to see any there? *A*. Yes, sir ; I made an effort and seen an instrument called a telephone and supposed it to be the instrument spoken of ; the one of which I had heard. I was looking and had made some inquiry, and was directed or came to a portion of the building where I saw on a counter some man's telephone, the name I don't remember. At that time or several times that I called, there was no one there to attend to it. I spoke to another party that had something else on exhibition, I don't recollect what it was, just near by, and I asked him whether there was any one there to attend or show the instruments. I was informed then there was no one there to show them.

Q. If you remember, please state what kind of an instrument it was that you saw there, and state what information you were able to obtain there regarding it and its mode of operation? *A*. There was a number of instruments placed on to a raised portion, something like a shelf ; that is, it resembled something like pigeon-holes, a box open in front, and each instrument at the back of it had an electro-magnet The number of instruments I don't remember. I don't remember of counting them. If I am not mistaken there may have been a dozen or more. Perhaps some were larger than others. I can't give you a much better description than that. I couldn't get any information about them. This attendant made some remarks about the instruments, but he didn't understand them and couldn't explain them. I was several feet from where the instruments were. They were on a raised place like a shelf, just about high enough for a man to speak into. That is the way it looked to me. I didn't go in behind the counter to examine them.

Q. Did you see any circulars lying around there referring to these instruments or any advertisements of them? *A*. I don't remember about that. It may have been.

Q. What was your impression as to the character of the instruments when you finally left them? *A*. I was impressed with the idea that they were instruments to telegraph by sounds, a certain sound to represent a certain letter of the alphabet. I am not certain how I got the idea, or whether any person told me that at the time, but that is the idea that I had.

Q. Do you know whether that was Gray's harmonic telegraph that you saw there or not? *A*. It didn't say "telegraph." I am confident it was called telephone. I didn't see the working parts of the interior except the electro-magnets. I took the name of the man and his address on a piece of paper and put it in my pocket, but I don't know what became of it. I don't know whether it was Gray's harmonic telegraph or not.

Q. Did you see any tuning-forks about it? *A*. I did not.

That was all he did during his entire visit to ascertain whether any one besides himself had actually entered upon this new and interesting field of invention and discovery. He spoke to no one about what he had done himself. He made no special effort to find out whether that which was on exhibition was in any respect like what he had at home ; neither did he when he got home, as far as the record shows, say anything to his neighbors or visiting friends about what he had seen or heard. He had apparently lost all interest in talking machines.

Not so, however, with his other inventions. The testimony shows that during the early part of 1876 he was much occupied in building an electric clock which he thought of exhibiting at the Centennial. This he did not do, however, but several days before he went to Philadelphia, or soon after, Rufus E. Shapley, a jeweler of Mechanicsburg, went on his suggestion to Eberly's Mills to look at the clock which he had made. Soon after that the clock was taken to Shapley's store in Mechanicsburg, and on the 8th of November, 1876, Drawbaugh, by an instrument in writing, transferred to Shapley a one-half interest "In the clock I am getting up, the said Shapley to pay for patenting the same." Shapley had then $2,000 in money, which Drawbaugh was anxious to have him invest in this business. The clock was taken by him to his shop so that it might be examined with that end in view, if it should prove to be useful. Some time after-

wards it was taken back to Eberly's Mills, where it remained until April 1st, 1878, or thereabouts, when a clock company was formed, and this clock, or another one substantially like it, was taken about the country for exhibition. For this, Drawbaugh was paid $500 and an interest in the profits.

On the 20th of September, 1878, he applied for a patent for improvements in batteries for electrical clocks. The patent was issued January 14th, 1879, to the members of that clock company. The enterprise does not seem to have been productive of any very great success.

In November or December, 1878, while this clock was on exhibition, Drawbaugh was introduced to Edgar W. Chellis. He had with him at the time a wooden model of a faucet that he wanted Chellis and another man to take a one-third interest in. An arrangement was made by which Chellis got a two-thirds interest, he paying $250 for it January 7th, 1879. On the 14th of the same month, Drawbaugh filed in the Patent Office an application for an improvement in rotary measuring faucets. After this applicat.on an interference was declared, March 27th, 1879, between Drawbaugh and David A. Hauck, who had filed an application. In his preliminary statement in this interference, Drawbaugh said he had conceived the idea of his faucet in the fall of 1869, and made a working model in 1877, and the Patent Office model was not completed until about the 1st of November, 1878. The case was closely contested and finally decided in favor of Drawbaugh, January 15th, 1880. The patent was granted to him and Chellis July 6th of the same year. In this contest, Jacobs and Hill, who afterwards became interested in the telephone claim, appeared as the counsel for Drawbaugh.

On the 2d of July, 1879, Drawbaugh filed another application in the Patent Office for an improvement in water motors. Chellis was to have in this also a two-third interest. On this application a patent was issued March 16, 1880.

DRAWBAUGH'S CONDUCT INCONSISTENT WITH HIS CLAIMS.

It is impossible to believe if Drawbaugh had in his shop, when he reached home from the Centennial, exhibits D, E, L, M, G, O and H, or even D and E alone, that he would have set himself to work in the first instance in developing the clock enterprise or perfecting his former conception of the measuring faucet, instead of calling attention to his great discovery of the telephone, which he was in danger of losing by a patent which had been issued to another, and which he could not but have known was even then attracting the greatest attention. In this connection it must be kept in mind that the theory of the defense, as stated in their answer is, that, Drawbaugh had at that time fully perfected his invention, and that while at first "he conceived that its range and capacity for usefulness to the public might be very greatly enlarged," he had before the date of Bell's patent, "notwithstanding his impoverished and embarrassed pecuniary condition and his utter want of proper mechanical tools," finally perfected his work. His conduct, therefore, is to be judged, not as of one who was still in the midst of his experiments and doubtful as to the results, but as of one who had arrived at the end, and completed his success. No man of his intelligence, with or without the enthusiasm on the subject which it is said he possessed, could remain silent under such circumstances.

As we have read the testimony, it is not even pretended that he took any of these instruments outside of his own village until May, 1878, when, as is claimed, he showed one to his friend Stees, in Harrisburg, whom he had known for years, who was the first to use, and in fact was then using, a Bell telephone upon a private line of his own between his office and his shops. This produced no results; and when afterwards, in January, 1879, Chellis was told that Drawbaugh had a phonograph and a telephone that he had invented, he gave it no attention, because, to use his own language, "I was interested in the faucet and motor business and wished to push them, and I did not think we could do much with a telephone, as Bell had a patent and I did not know that he could antedate it."

Again, when speaking of a conversation he had with Drawbaugh he said, "I advised him to drop the telephone, as he could not antedate Bell. He said he didn't know about that; that he had been working on it a good while. It was his way of expressing himself when I would say "You can't antedate Bell." He would say, "I don't know about that; I have been working at it a good while."

This, it must be remembered was in 1879, after the telephone had become a success, and after it had been a year or more in use in Harrisburg where Chellis lived. It is impossible to believe that either Chellis or Drawbaugh was ignorant of the approximate time of Bell's invention, which had been the subject of frequent newspaper comment from the time of its exhibition at the Centennial. The subject was often referred to in the Harrisburg and Mechanicsburg papers, and it is not for a moment to be supposed that all these various articles escaped their attention. Under such circumstances, if it were true that Drawbaugh had made his D and E as is now claimed, in February 1875, he certainly would have said so, and he would not have contented himself with so doubting an answer to Chellis' suggestion of his inability to antedate Bell, as that which Chellis now says he gave.

Another important fact in this connection is one which is proved by the testimony of Andrew R. Keifer, who from 1863 had been division telegraph operator having charge of the middle division of the Pennsylvania railroad, and resided in Harrisburg from 1863 to the winter of 1881. He was a member of an electric firm in that place, engaged in the manufacture of burglar alarms, instruments for the signal bureau, etc. He had also since 1876 kept a place for the sale of electrical supplies. He had known Drawbaugh since 1876, and probably before. Drawbaugh met him on different occasions in the course of their acquaintance and talked with him on electrical matters. In the course of their acquaintance, Drawbaugh showed him an electrical fire-alarm apparatus, and the working of his electrical clock, but the subject of telephone was never alluded to between them until the summer of 1881 when this occurred (we quote from the deposition of Keifer).

> In the summer of 1881 I took my wife out for a drive and went over to see his works, never having seen them, and having promised him to come and see him some time; my wife not caring about going to the shop remained in the carriage, and I went through alone with Mr. Drawbaugh. He showed me through the shops and introduced me to Mr. Chellis, and showed me parts of the water-motor and some other things of his getting up. On account of my wife being in the carriage alone I did not stay long. As I stepped into, or was just in the carriage, Mr. Drawbaugh said: "I forgot to show you my telephone! I did not get out again to go and see it, and I drove away without seeing it, expecting to see it again, but I have never got over to the shop since.

This was after the suit of the Bell company against the People's company was begun, and of course after the matter got into the hands of Chellis and his associates. It is no answer to the criticism of Drawbaugh's conduct in this particular to say, as was said in the argument, that one reason why he did not speak or apply to every man with whom he had a personal acquaintance was that he was ridiculed by his neighbors; that his invention was considered a humbug by them and of no commercial value. Bell's success was proclaimed in the Harrisburg *Patriot* as early as February 26, 1877, and the age of ridicule was then past. If Drawbaugh had at that time in his shop the machines it is now claimed were there, complete as they now are, in August, 1876, and most of them before, there cannot be a doubt that he would have taken them to some place where they could be tried, and show that they

would do what he had all along claimed for them. All he had to do at any time after he came back from the Centennial was to take any pair of his little instruments to his friends at Harrisburg, attach them to a line wire and show what he had. They were men who could appreciate the telephone and help him, if it was, as he now says it was, a success. It would certainly have been easier then, within two years of the time the first of them was made, and within a year of the date of Bell's patent, to show that he antedated Bell, than it was three years afterwards when he was brought into the controversy through the instrumentality of his associates, not, as must be evident to all, to get a patent for himself, but to defeat that of Bell.

In this connection it is specially significant that the application which it was claimed was made for a patent on the 21st of July, 1880, and the specification of his invention which was then written out, has been purposely and designedly kept out of the case, although their production was demanded. They were written before this suit was begun, and it is impossible to believe that they would have been withheld, at least upon the call of the opposite party, if they were in all respects consistent with the subsequent development of the case. The excuse given by counsel at the time, that they were in the secret archives of the Patent Office, and if produced and published in this case would possibly invite the filing of contesting applications and result in an interference and additional litigation, besides unnecessarily prolonging the taking of testimony and increasing the expenses, we cannot accept as satisfactory, in view of the fact that in the answer, it was said that one object of filing the application "was to procure interference proceedings to be instituted against the patent of Bell, in order that Drawbaugh might be adjudged by the Commissioner to be, as he rightfully is, the original and first inventor."

We have not overlooked the depositions that have been taken in such large numbers to show that Drawbaugh was successful with F, B, C, I and A, before D and E were made. They have been studied with care, and if they constitute all the testimony in the case it would be more difficult to reach the conclusion that Drawbaugh's claim is not maintained. But in our opinion their effect has been completely overcome by the conduct of Drawbaugh, about which there is no dispute. From the time of his visit to the Centennial until he was put forward by the promoters of the People's company, nearly four years afterwards, to contest the claim of Bell, he was silent, so far as the general public were concerned; while if he had really done what these witnesses say he did, he would certainly have spoken. There is hardly a single act of his connected with his present claim, from the time he heard, before going to Philadelphia, that some one else had invented a telephone which was on exhibition at the Centennial, that is not entirely inconsistent with the idea of a complete discovery or invention by himself which could be put to any practical use.

It is not pretended that what he did was done in private. He had influential friends, with ample pecuniary resources to help him in bringing out his inventions when they promised success. He easily got aid for his clock and for his faucet. The news of Bell's invention spread rapidly, and it took but a few months to demonstrate to the whole world that he had achieved a brilliant success. No one can believe that the public would be kept in ignorance of the invention until four years afterwards, when a special despatch from Washington to the *Cincinnati Commercial* announced a telephone combination to have entire charge of the telephone in this country.

DRAWBAUGH FAILS TO REPRODUCE HIS ALLEGED RESULTS.

But there is another fact in this case equally striking. As has already been seen, F, D, C, and I were in no condition for use when they were produced and put in evidence. They were mere remains. No one but Drawbaugh himself could state how they were made or how they were to be used. He undertook to reproduce some of them, especially F and G. This was in the latter part of 1881, while the testimony was being taken. The Bell company proposed that they should be tried, to see if they would do what the witnesses said had been done with the originals, which the remains show must have been exceedingly primitive in their character. The testimony also shows that when they were originally used, by or in the presence of the witnesses, no particular care was taken in their adjustment. They were lying around in the shop or placed upon shelves. Some say that when the experiments were made they were held in the hands or allowed to stand on a table In order to reach satisfactory results Drawbaugh himself said in his deposition :

> I had persons in the cellar reading printed matter, some advertisement or something, and I could hear the words that were read; and at other times I would go down into the cellar and read something and come up, and they would repeat the words to me that I had read.

The proposition of the Bell company was accepted, and the reproductions were tried in March, 1882, under the most favorable circumstances. It is substantially conceded that the trial was a failure. Occasionally a sound was heard and sometimes a word, but it would not transmit sentences. At the time of these experiments, F, which was the transmitter, was placed on a table as Drawbaugh said it was originally.

Two years afterwards other reproductions were presented, differently constructed and used in a different way. Those would talk, but they were neither the same nor used in the same way as the originals. To our minds, the result of the experiment conclusively shows that the original instrument could not have been of a construction similar to the reproductions, and that what they had done was produced by some other means.

We do not doubt that Drawbaugh may have conceived the idea that speech could be transmitted to a distance by means of electricity, and have experimented upon that subject. But to hold that he discovered the art of doing it before Bell did, would be to construe testimony without regard to the ordinary laws that govern human conduct. Without pursuing the subject further we decide that the Drawbaugh defense has not been made out.

THE ALLEGED FRAUD IN THE PATENT OFFICE.

Another objection to Bell's patents put forth in the oral argument of Mr. Hill, and in the printed brief signed by him, and in that signed by Mr. Dixon is, that the application as originally filed in the Patent Office, did not contain his present fourth claim or any description of the variable resistance method, and that all which now appears in the specification on that subject, including the fourth claim, was surreptitiously interpolated afterwards. Bell's application was filed February 14th, 1876, and afterwards, during the same day, Elisha Gray filed a caveat in which he claimed as his invention "the art of the transmission of vocal or other sounds or conversation telegraphically, through an electric circuit," and in his specification described the variable resistance method. The precise charge now made in the printed brief of Mr. Hill is—

> That Mr. Bell's attorneys had an underground railroad in operation between their office and Examiner Wilber's room in the Patent Office, by which they were enabled to have unlawful and guilty knowledge of Gray's papers, as soon as they were filed in the Patent Office; and that an important invention and a claim therefor were bodily interpolated into Bell's specification between February 14th, 1876, and February 19th, 1876, by Pollok, in consequence of the guilty knowledge which the latter already had of the contents of Gray's caveat before the declaration of interference with Gray on February 19th.

So grave a charge, made in so formal a manner, is entitled to consideration. It involves the professional integrity and moral character of eminent attorneys, and

requires us to find from the evidence, that after Bell swore to his application on the 20th of January, 1876, and after the application thus sworn to had been formally filed in the Patent Office, an examiner who got knowledge of the Gray caveat put in afterwards, disclosed its contents to Bell's attorneys, and they were then allowed to withdraw the application, change it so as to include Gray's variable resistance method, over Bell's signature and over the jurat, and then to restore it to the files thus materially altered, as if it were the original, and all this between February 14 and February 19. Although much stress was laid in the argument on the fact that what purported to be a certified copy of the specification of Bell, as found in the file-wrapper and contents printed in the Dowd case, differed materially from the patent, the occasion of these differences has been explained in the most satisfactory manner.

We entertain no doubt whatever that the specification as now found in the patent is precisely the same as that on which the order to issue was made. If any alterations were made they were all done before February 19, and the fair copy which is now found on the files of the Office is precisely as it was when the order for the patent was granted; not a shadow of suspicion can rest on any one.

All that remains, therefore, on which to rest this serious charge, is that in a paper handed by Bell to George Brown, of Toronto, describing his invention, and which was intended to be used in England to secure a British patent, there is now claimed to be an interpolation which in the American application is not to be found. It is but right to say that during the whole course of the protracted litigation about the Bell patent, no argument was ever presented based on this discrepancy until the brief of Mr. Hill was filed in this Court on the 18th of January 1887, six days before the argument on these appeals was begun. So far as we are advised, nothing has ever before occurred in the cases that seemed to make it necessary to prove when the variable resistance method, or the fourth claim, was put into the American application, or why it was left out of the paper handed to Brown. It seems always to have been assumed, until the cases got here, that because it was in the American patent it was rightfully there. Certainly there is nothing in the pleadings in any of the cases to direct attention to the materiality of this fact. A comparison of the paper handed to Brown with the American application shows that they differ in more than thirty different places, besides those which relate to the variable resistance method and the fourth claim. The differences are generally in forms of expression, this indicating that one was written after the other, and evidently for the purpose of securing greater accuracy. The paper handed Brown was merely a rough draft and not a fair copy, for the record shows that it bears on its face the evidence of numerous erasures and interlineations. Bell says in his testimony that he began writing this specification in October 1875, and wrote and rewrote it a number of times, and finally adopted that mode of expression which seemed to him best to explain the invention and the relation which one portion bore to another. He visited Brown in Canada in September and again in December 1875. An arrangement was made between them on the 29th of December, at the last interview, by which Brown was to interest himself in getting out the British patent. Other inventions besides the telephone were included in the contract entered into for that purpose. Bell returned to Boston on the first of January, and immediately set himself to work to complete his specification. It was taken to Washington by Mr. Hubbard, about the 10th of that month, and delivered to Pollok & Bailey, his attorneys. It was then examined by his attorneys and found correct, and a fair copy made, and then returned on the 18th to Bell, for his signature. It was signed and sworn to in Suffolk county, on January 20th, and immediately returned to the attorneys. Afterwards Mr. Pollok met Bell in New York, and it was again gone over with care by the two together. No change whatever was made in it at that time and Mr. Pollok took it back with him to Washington.

On the 25th of January, 1876, Bell met Brown, who was then on his way to England, in New York. It is now assumed that the papers which Brown took to England was handed to him then; and because the variable resistance method in the fourth claim was not in it, it is argued that it could not have been in the American specification at that time. But no one has said when the paper was actually handed to Brown. Bell says he cannot tell, but it must have been after he made his contract with Brown on the 29th of December. As the American specification was signed and sworn to five days before the interview with Brown on the 25th of January, and the paper of Brown differs from it in so many particulars besides that now in question, it would seem to be clear that the paper was a copy of some former draft that Bell had made and possibly taken to Canada in December, not that which was perfected afterwards. As the specification which had been prepared and sworn to, was a fair copy without erasure or interlineation, the fact that the paper handed to Brown was not a fair copy would imply that it was not intended to be an exact transcript of the other.

At any rate, the bare fact that the differences exist under such circumstances is not sufficient to brand Bell and his attorneys and the officers of the Patent Office with that infamy which the charges made against them involves. We therefore have no hesitation in rejecting the argument. The variable resistance method is introduced only as showing another mode of creating electrical undulations, and that Bell had had his mind upon such a method is conclusively established by a letter which he addressed to Mr. Hubbard on the 4th of May, 1875, and which is in the Dowd record, introduced into the Overland record by stipulation. Its insertion in his final draft of his specification is another proof of the care with which the work had been done.

INCORPORATION OF THE BELL COMPANY.

In the case of the Clay Commercial Co. objection was made to the sufficiency of the proof of the incorporation of the American Bell Telephone Co. The first point is as to the act incorporating the American Bell Co., which authorized certain persons therein named to form a corporation; and second the certificate of the Secretary of the Commonwealth, in the form required by Section 111, Chapter 224, that certain persons, among whom were the members of this company, under the name of The American Bell Telephone Co., were legally organized. This section made such a certificate conclusive evidence of the existence of a corporation organized under that act. The authority granted by the special act to the persons named to organize as a corporation in this way, gave them the authority to select a corporate name and also made the statutory certificate conclusive evidence. The objections to the proof of title are not, in our opinion, well taken. We do not think it necessary to add to the length of this opinion by referring to the testimony upon that point.

THE SECOND BELL PATENT.

This disposes of all the cases so far as the patent of March 7th, 1876, is concerned. It remains now to consider only the other patent. It received but little attention by counsel or court in either of the cases below. In the Dolbear case it was by consent excluded from the decree.

In the case of the Clay Commercial Co. it was alleged in the answer that substantial and material parts of the things described and claimed were described and claimed in a prior British patent taken out December 9th, 1876

and inasmuch as the foreign patent does not bear the same date, if the American patent is not limited it is void. This point has not been pressed in the argument. In our opinion it has been settled by the decisions of this court in *O'Reilly* v. *Morse* and in *Siemens* v. *Sellers* at the present term, that the effect is not to render it invalid if it is for the same invention, but only to limit its term. The patent in itself is for the mechanical structure of an electric telephone, to be used with the electrical action on which the first patent rests. The *third* claim is for the use, in such instrument, of a diaphagm made of a plate of iron or steel, or other material capable of inductive action; the *fifth* is for a permanent magnet; the *sixth* for a sounding box; the *seventh* for a speaking or hearing tube, and the *eighth* for a permanent magnet and plate combined. The claim is not for these several things, but for an electrical telephone in the construction of which those things or any of them are used. Hence the fifth claim is not anticipated as was decided in the Molecular case below. The patent is not for a magnet, but for a telephone of which it forms a part. To that extent the decree in that case was erroneous.

THE DECREE.

It follows that the decree in each of the cases so far as it is in favor of the Bell company and those claiming under it, must be affirmed, and that the decree in the Molecular case so far as it is against that company on the fifth claim of the patent must be reversed, and a decree directed to that extent in its favor. It is accordingly so ordered.

Mr. Justice GRAY was not present at the argument and took no part in the decision of these cases.

JUSTICES BRADLEY, FIELD AND HARLAN DISSENT.

[At the conclusion of the reading of the opinion of the Court, Mr. Justice Bradley made the following remarks.]

Mr. Justice BRADLEY—Mr. Justice Field, Mr. Justice Harlan and myself are not able to concur with the other members of the Court in the result which has been reached. The point on which we dissent is the question of Drawbaugh's invention. We think that Drawbaugh did anticipate the invention of Mr. Bell. We think that the evidence to that point is so overwhelming, both with regard to the number and character of the witnesses, that it cannot be overcome. Of course, it is a question of fact depending upon the weight of the evidence, and involves no question of law, and therefore it is a matter that does not require much observation on the part of those who dissent from the opinion, which is very ably drawn, and undoubtedly presents the whole case with great force. But on this point we cannot concur in the views of the court. We think that Drawbaugh did have an instrument in his shop as early as 1869, which used the variable resistance instrumentality in transmitting articulate speech to a distance, by means of electricity, and was distinctly heard and understood. That is the whole invention, so far as variable resistance is concerned.

We also think that as early as 1871, he did produce an instrument employing the magneto-electric instrumentality altogether, substantially the same as that which is claimed in Mr. Bell's patent. In the one case, with regard to the variable resistance principle, over 70 witnesses were produced. The evidence of some of them may have been shaken with regard to the time that they had in mind; but the evidence of the great majority of them is not shaken at all. They were mostly plain people of the country, but they heard the words, and that is a matter that they could not be mistaken about. It did not require science nor literature nor refinement to understand that.

In regard to the other instrument, some 40 or 50 witnesses were produced who saw it. Many of them heard the language produced through it, and a number of witnesses who did not hear the language produced through these instruments, saw them or heard them talked about, so as to fix the time that they were in existence, and it seems to us that on this subject of time and of result, there is such a cloud of witnesses that it is impossible not to give credence to them. There is no doubt that Mr. Bell's merits are very great in appreciating the importance of the discovery, and in bringing it before the public in such a manner as to make it appear to be what it is, one of the most important discoveries of the century. He was a man whose professional experience and whose scientific attainments enabled him to see at a glance the importance of it. Drawbaugh was a different sort of man. He did not see it. Had he done so, he would have taken measures to interest persons with him in it, and have brought it out. He was a mechanic, a plain mechanic, somewhat better instructed, perhaps, than most ordinary mechanics, a man of more reading, a man of more intelligence. But he looked upon what he made more as a curiosity than a matter of speculation, a matter of financial importance or of importance to the public. That is the way we view his condition of mind in regard to it, and explain why he had not taken more pains to bring it forward to the notice of the public. It is the tendency of the human mind to attach importance to the results and inventions of those who have achieved eminence. Watt was the idol of the British nation, from the time of his first invention of the steam-engine until the day of his death, and until the present time; and everything that was invented about the steam-engine was attributed to him. It was the glory of England, the glory of Watt, and of course every patriotic British subject would hoot at anything it was claimed Watt did not invent, or attribute it to him. That is a principle of the human mind on which we think a great deal may be explained with regard to the feeling towards this important service which Mr. Bell has rendered with regard to this invention. The plain mechanic of Pennsylvania is of no account. The scientific and illustrious—for he is illustrious—Mr. Bell, it cannot be but that he did invent this thing! And yet if Mr. Bell on the 14th day of January (I think it was) or February, when he applied for his patent at the Patent Office, had had in his laboratory the things that Drawbaugh had, he would have been filled with an excitement far exceeding that which has animated the great inventors of the world when they made the discoveries they have made, and he would have exclaimed: "Eureka! Eureka!" He would have appreciated it, if Drawbaugh did not.

What had he when he applied for his patent? On the 10th of June, 1875, they thought they heard something, but were not sure; but he knew the principle and he patented it. Up to the time of making his application for a patent they had not succeeded in producing intelligible speech, more than a word or two; perhaps a word or two. If Bell had done at that time as much as Drawbaugh had done according to the evidence, he would have had no hesitation in claiming the greatest discovery that the world has seen in the present century.

This is an outline of the views which we have on this subject. We have nothing to say depreciatory of Mr. Bell at all, for he has real merits; but we think that this obscure mechanic did do the thing, and that he is entitled to the merit of being the first inventor.

We will take an opportunity within a few days to write a further statement and file it.

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. VII. NEW YORK, APRIL, 1888. No. 76.

SPECIAL NOTICE.—To afford an opportunity to become acquainted with THE ELECTRICAL ENGINEER, *the publishers will send it to any new address for* THREE MONTHS *for* FIFTY CENTS.

If any subscribers to THE ELECTRICAL ENGINEER have failed to receive the Supplement issued March 22, *containing the full text of the judgment of the United States Supreme Court in the Appealed Telephone Cases, as delivered March* 19, *they will be promptly supplied on application to the publishers.*

JUDGE MORRISON R. WAITE, Chief Justice of the United States Supreme Court, died at Washington, D. C., March 23.

A VICTORY FOR THE PATENT LAW.

IT is quite difficult to convey an adequate conception of the increase in the value of industrial property based upon patented inventions, which must directly result from the position taken by the Supreme Court of the United States, in the recent decisions in what are known as the Telephone and the Glycerine cases. Looking at the question in its broadest sense, wholly irrespective of particular corporate or individual interests, we do not hesitate to affirm that the public has abundant reason to congratulate itself upon the advanced and unmistakable ground which is now occupied by our highest judicial tribunal in respect to the patent law.

The theory on which the patent legislation of every country is based is that of conferring an exclusive monopoly, of limited duration, upon the original inventor or discoverer of any new art, machine or manufacture, by way of compensation to him for conferring the benefits of such invention or discovery upon the public. The patent is virtually a contract with the government, whereby the inventor is permitted to make what profit he can, and in what manner he may see fit, out of his fellow-citizens during a term fixed by the statute at seventeen years, in order that the community may for ever afterwards enjoy the unrestricted use of the invention, together with all its profits and advantages. Such a bargain is certainly a fair one, and experience has shown it to be a remarkably advantageous one, so far, at least, as the public is concerned; yet in the face of this fact, one after another of the prominent inventors who have rendered the American name illustrious, and who have contributed beyond computation to the industrial progress and wealth of the country, has found himself literally a target for an unceasing torrent of misrepresentation, opprobrium and abuse. We can scarcely recall an exception. Fulton, Whitney, Morse, Goodyear, Howe, McCormick, and, finally, Bell, each has had to endure it in turn with as good grace as possible. But time brings out the truth at last, and the odium of yesterday becomes the applause of to-day.

A number of interesting observations might be made upon the findings of the court in the cases to which we have referred, but we have space to consider only a few of them.

The opinion in the telephone case reaffirms the basic principle, that the person through whom the public derives the benefit of the discovery is the person upon whom the law seeks to confer the reward. It is Bell, not Ries nor Drawbaugh, to whom we are indebted for the benefits, whatever they may be, of the telephone. In the well-known case of the Brush arc lamp, decided adversely to the patent some years ago, the result must have been to sustain the patent, had the inventor's right not been barred by a clearly proven "prior public use" of the device by another, by which phrase it should be understood is meant, not merely a use in public, but a use, although for a short time, for actual business purposes.

We are further clearly instructed in both these cases that an absolute distinction exists between a patent for an art, method or process, and a patent for a machine. While an invention technically termed an art may be nothing more than a new way of using an old machine, it may yet possess patentable novelty in the highest degree, one evidence of which may be the novelty or the great utility of the new result.

Moreover, the important principle has been reaffirmed—and in view of some recent decisions of the federal courts, such reaffirmation would seem to be highly desirable and necessary—that the right of the inventor of a valuable improvement ought not to be abridged by restricting it to the particular embodiment, often a very imperfect one, in which he first gives it the public. The highest order of inventive talent is frequently found dissociated from even an average degree of mechanical dexterity; but to the uninstructed mind the work of the skilful mechanic is often sufficient to wholly eclipse the conception of the thinker, without which the invention in any form could have had no existence.

The opinion in the glycerine cases reaffirms some of the above fundamental doctrines, and teaches the additional lesson that the piracy of patented inventions is not, in a commercial sense, uniformly a profitable pursuit. The infringers, it appears, in this instance appropriated the patented process, but sought to avoid responsibility by employing a different apparatus to work it. They have now had the great truth hammered into them by the Supreme Court, to the tune of $320,000, that a patent for an art is not necessarily restricted to the patentee's specific apparatus, and they have furthermore learned, doubtless with some surprise, that they cannot escape by compulsorily handing over the license fees as paid by honest users, but are to be compelled in addition to disgorge all the profits which they have accumulated by their wrongful and intentional appropriation of the patentee's property.

Finally, the result in both these cases illustrates the importance of properly preparing and prosecuting the application for a patent. If the principal claim of the Bell patent had been but a trifle broader in its scope, it could scarcely have escaped the fate of the celebrated eighth claim of Morse, while, on the other hand, if it had been less broad, it must necessarily have failed to cover some of the many ingenious modifications of which the original invention has been found to be susceptible. Moreover, had the evidence shown the slightest basis for the allegation, so persistently made, that Bell's specification had been improperly amended while in the patent office, it is clear that nothing could have saved the patent.

The finding of the Supreme Court in the telephone case, although doubtless somewhat of a surprise to the general public—which has from beginning to end been persistently and completely misled by the unscrupulous mendacity of the newspaper press—was in effect precisely what had been anticipated in legal circles as well as by laymen familiar with the actual facts. The dissenting opinion, which relates merely to a disputed question of fact, does not in the least diminish the force of the conclusions which we have indicated. The result is a well-deserved triumph for the principles of the patent law with which the inventors of America, and the owners of all property based on inventions have good reason to feel well pleased.

THE PROBLEM OF ELECTRICAL DISTRIBUTION.

At the present time, the columns of the electrical journals are filled, almost to the exclusion of everything else, with literature relating to the distribution of electric energy by alternating currents and induction apparatus. This same subject occupied a prominent place in the proceedings of the National Electric Light Convention at Pittsburgh, where some admirable papers were read, which were printed in our last issue. On the other side of the Atlantic, the Society of Telegraph Engineers and Electricians have recently given up several successive meetings entirely to the discussion of the same topic. The commercial importance of the issues involved, renders it desirable to reproduce some of the more valuable of these papers and discussions, and part of them will be found in another part of our present number.

Not the least interesting of the various contributions to this discussion is the recent publication of the Edison Electric Light Company in advocacy of the direct method of distribution, in which the following assertion is made respecting the alternate current method with converters:

> The large engine-unit requisite, the low economy of the generator as compared with direct current dynamos, the extra loss of energy due to the interpolation of the converter, and the constant demand upon the station made by the converters, irrespective of the work they are doing, all combine to render the system *the most uneconomical yet offered to the public.*

The figures offered in substantiation of the above statement assume the loss in the dynamo to be 10 per cent for the direct as against 30 per cent for the alternating; in the line, 4.7 per cent for the direct as against 5 per cent for the alternating, besides a loss of 4.8 per cent in the alternating converters; total loss of energy 14.7 as against 35.3 per cent, in favor of the direct method.

In reference to this proposition, a contemporary remarks:—"One thing is certain, the advocates of the alternating current system must reply to the challenge, and that speedily, if they wish to hold the position which they have already gained." But we would remind our esteemed contemporary that assertion is not argument; and moreover the question at issue is one which is wholly incapable of being settled either by assertion or argument. If it is indeed true that the indirect method of distribution involves a loss of over 35 per cent of the energy in distributing it, as against 15 per cent by the direct method, something a great deal more potent than counter-assertion will be requisite to enable the "advocates" of the alternating system to "hold the position they have already gained." That exceedingly hard-headed and practical person, Mr. R. E. Crompton, put the matter in a nutshell, when he told the London electricians that the thing wanted was a statement of the efficiency "right out, from the coal-bills to the electricity sold to the consumers."

Every system must start from "taw," that is to say, the price of fuel which all must pay. At the other end of the line the price which the average consumer is willing to give per candle-power for his light is likewise within narrow limits a fixed quantity. Hence the real question, and the only one is, by which method can a given amount of light be produced at the point of consumption at the least cost, remembering that one important element of this cost, is the interest on the original investment, that is, on the cost of the plant.

We now have in this country a large number of central station plants in successful operation both by the direct and the indirect methods of distribution. It is not going to take a very long time, under these circumstances, to determine which of the two methods is, all things considered, the most economical.

Two or three considerations may however be adverted to, that they may not be wholly lost sight of. First.—As a direct current dynamo is in point of fact nothing more than an alternating dynamo, plus a commutator for straightening its current, there is no reason *per se*, why the efficiency of one should be any greater than that of the other. Second.—As it is indisputable that with a given loss of potential in the mains and feeders, the weight and cost of the copper required is inversely as the square of the potential employed, it follows that only one twenty-fifth as much copper will be needed for a potential

of 1000 volts as for a potential of 200 volts, to which must be added on the other hand, the cost of the converters. But the cost per lamp of any converter is a constant quantity and does not increase with the distance from the central station; while on the other hand the cost of copper per lamp in the mains and feeders increases as the square of that distance. These facts render it demonstrably certain that there must be an area surrounding every central station, varying somewhat in extent with the particular circumstances of each case, beyond which the direct method cannot hope to compete successfully with the indirect method. Third.—The difference in the cost of service and interior wiring is not properly an element in the calculation. High potential lamps and small service wires can be used just as well with the indirect as with the direct method, were it not for the fact that the incidental advantages of low potential lamps have been found to more than offset the slightly greater cost of wiring.

The controversy as to the relative merits of the two methods of electrical distribution, like that between paddle wheels and screws in steam navigation, or between broad and narrow gauges in railroading, may be trusted to settle itself. If an innovation possess intrinsic merit, the most violent and long continued objurgations on the part of its opponents are usually received with stony indifference on the part of those who find it profitable to adopt it, while if it is without merit, the public may be trusted to find it out, and that at an early day, in spite of the most ingenious and plausible arguments in its favor.

THE PRACTICAL SIDE OF INCANDESCENT LIGHTING.

Among the many excellent papers presented at the Pittsburgh meeting of the National Electric Light Association, those by Messrs. Wm. Lee Church and T. Carpenter Smith, easily carry off the honors as contributions of the highest importance to the progress of the art of electric lighting; they therefore deserve more than a passing recognition. They are admirable exemplifications of the work which is being done in this country by men in whom a thorough training in theoretical steam and electrical engineering has been supplemented by extensive practical experience and by unprejudiced and intelligent observation.

Each of these papers may be characterized as a plain simple statement of facts, and of deductions therefrom, eminently adapted to appeal directly to the commonsense of the average listener. There is a conspicuous absence of fine-spun theory and of mathematical generalization which, however valuable in their place, could add little if anything to the force of the arguments deduced from the facts so clearly and convincingly set forth.

Incandescent electric lighting has now been before the public for eight years, but it cannot be denied that up to the present time, the financial results have been for the most part, extremely unsatisfactory. A careful study of these two papers goes far to disclose the causes of disappointment. From the nature of the case, the margin of profit in incandescent lighting is rigidly limited, by the price of fuel on one hand and the price of light on the other. Inefficiency, either in the motive power, the electric plant, or the management, in the long run is sure to prove fatal. In view of the mistakes which have been made, in matters large and small, in both the mechanical and electrical details of electric lighting plants, the only reasonable cause for wonder is that the results have been no worse.

Grateful acknowledgement is due to Mr. Smith, in particular, for the candid manner in which he has detailed his own mistakes and failures as well as his successes. Like the true artist, he has grasped the significance of shadow as well as of light, and realizes that a picture containing lights without shadows can give but an imperfect representation of the subject under treatment.

DON'T.

The great activity prevailing in this country at the present time in the principal electrical industries, is very naturally attracting the attention of many young men abroad, especially in England, who after graduating from some technological institution, and providing themselves with unexceptionable letters of introduction to some one in New York, speedily find their way across the Atlantic, in full confidence that remunerative employment awaits them immediately upon arrival.

Our transatlantic contemporaries cannot do many of these young gentlemen a greater service, than to persuade them, if possible, to accept and act upon the celebrated advice of *Punch* to those about to marry. While it is true that most of these persons ultimately find employment in some capacity or other, yet not a few have been compelled to undergo experiences which are, to say the least, exceedingly humiliating to a sensitive soul. Many of them are supplied with barely more than enough money to land them in New York; they then learn, to their dismay, that almost all the electrical establishments of importance are situated at distances varying from 200 to 1,000 miles or more from the metropolis, and can only be reached by an expensive railway journey. They further find, usually to their very great astonishment, that their letters of introduction and of recommendation, so indispensable in Europe, are of little more account on this side of the ocean than so much waste paper. A man in this country always expects to apply for a situation on his own merits. "Influence" goes for little or nothing. If an employer happen to have a vacancy and the applicant appear to be capable of filling it, he is likely to have a chance to try, even though he may be an utter stranger. If he were backed by a personal letter from the President of the United States, it would as a rule make very little difference. One thing is absolutely essential—the candidate must know how to do work with his own hands, and skillfully at that, or he will find there is no room for him in an American establishment.

We do not say this to discourage our English cousins, for we are well aware that many of the most successful electrical engineers in America have come here as young men, from across the seas. But it will save much disappointment if those who may come hereafter start with a definite conception of the industrial conditions and customs of this country, which differ so widely in many respects from those to which they have been accustomed at home.

OUR transatlantic contemporaries are sometimes unintentionally funny. Witness the following, from the editorial columns of a recent issue of the London *Electrical Review*.

That there is a great future for alternating transformers, we have no doubt, for they have indeed a very important present. We can only regret that the system can never give the immunity from accident which a system admitting of storage would be certain to ensure.

Accidents will happen, even to so well regulated a system as that of gas supply. Last Saturday evening a man at the Canterbury gas works turned a handle the wrong way, and instead of increasing the illumination of the city, plunged it into darkness. What a cumbrous proceeding was necessary to rectify this small error! Some hundreds of individuals must have been momentarily at work to undo the work of one. How simple would have been the process if the electric light had been the illuminant—the turning back of the handle would have put all as it was before!

If we were the Archbishop of Canterbury, we would compel every householder, under pain of excommunication, to equip his premises with a storage-tank to hold a sufficient supply of gas for 24 hours' consumption. The illumination of a cathedral city at the mercy of a stupid gas employé, who is clearly unable to distinguish his right hand from his left! Such a system "can never give the immunity, etc."

MR. GOULD having returned from his wanderings in foreign climes, we hope some trusted friend like Mr. Sage or Mr. Field may be deputed to break to him, as gently as may be, the direful intelligence of the impending overthrow of the Western Union monopoly. A new compound of the most energetically explosive character has been discovered, which is to do the business. It is a combination of a Siliconized Copper Wire, and a Machine. It was discovered by Mr. Craig. When we consider what stupendous political convulsions have been precipitated by the agency of Machines, and even by the mere pulling of Wires, we almost feel sorry for Mr. Gould. Mr. Craig's new pamphlet fairly bristles with Startling Facts. We trust General Eckert will keep this brochure out of Mr. Gould's sight as long as he possibly can.

OBSERVATIONS.

Modern Light and Heat, in a recent issue, thinks it remarkable that no one, "so far as it is aware," has ever utilized in practice the suggestion offered by M. Bissot in 1878, to improve upon the ordinary winding of electro-magnets, by returning the wire after completing a layer of convolutions straight to the point of departure, there to begin the next layer, instead of winding it backwards. The statement was made by M. Bissot that by this mode of winding a gain of one-third in power was obtained.

The writer observed this statement in 1878 when it was widely published, and was, as doubtless many others were, considerably impressed with the idea that there was something in it. He tried it, and found that there was nothing in it, and indeed, upon reflection, it is difficult to see where or why any improvement could be expected.

The experiment was also similarly tried by W. H. Preece, who records his results on page 468 of vol. vii. of the Journal of the Society of Telegraph Engineers. These results were identical with those obtained by the writer, and Mr. Preece concludes his statement by saying: "In no case was anything gained by the new method of winding as claimed, but, on the contrary, the old method proved itself to be superior under all circumstances."

It is easy to see that the new mode introduces difficulties into the work of winding, and that the addition of a longitudinal ridge of wire for each layer does not by any means decrease the size or improve the appearance of the helix.

We may naturally infer from the fact that M. Bissot has since his first published statement "lain low," that he was a little premature in his announcement, and that his later experiments in this direction have not fulfilled the promise of their youth.

* * *

THE morning papers of Feb. 13th, 1888, comment upon the death of Hon. Edward Farrar of Keene, N. H., which took place on the previous Saturday, as follows: "He actually invented the first rude telephone in this country, although, owing to his extreme modesty, he never pushed his claim."

This statement would doubtless be generally received with incredulity, were it not that the ascription of extreme modesty, an attribute well known to be a characteristic of original inventors of the telephone, puts it beyond the pale of question. But where are Cushman and his frogs?

The researches of Mr. Farrar have been set forth by Prof. Dolbear in some of his papers on the telephone, and are likewise referred to in a letter published in the *Scientific American* of April 26th, 1879.

* * *

THE necessity of protecting all watches, save and excepting the "Waterbury," from the dire results of magnetization, is now universally recognized; for, though watches once magnetized are curable, the curing process gets to be a bore when it is frequently required.

We are familiar by this time with one or two modes of preventing this magnetization. The first expedient was to encase the watch in an iron shield, this being based upon the well-known ability of iron to short circuit, so to speak, the damaging magnetic rays. It seems probable that to be perfectly efficient the screen applied will have to be thicker than it now usually is.

The other plans which are presented for the favorable consideration of electricians are the construction of the balance, hair-spring and escapement of some non-magnetic metal or alloy. Palladium being evidently a favorite metal for use, either alone or mixed with some other metal or metals. The Paillards, and also the Waltham Watch Co. have adopted the latter mode, the first concern patenting their materials and devices, and the last-named preferring to hold them as a trade secret.

Rumor has it that only two men know the secret now, and that they may die at any moment. It seems as if the abstracts of the old English electrical patents resemble the average patent medicine in that they are ready for every emergency. They are not taken by surprise with the non-magnetic watch. A party by the name of Ulrich, patents on April 22, 1887, "A mode of compensating for the expansion and contraction of the balance spring under variations of temperature, by the employment of such materials for the balance as are not subject to magnetic influence, such as platina, palladium, etc."; and on January 14th, 1856, the same person patents, "Improvements in the compensation balance, destroying its tendency to be affected by terrestrial magnetism or local attraction, on iron ships in particular. In old chronometers a thin armature of iron is used, and in new ones the use of metals not subject to magnetism is recommended, such as brass, silver, aluminum or palladium; all of which goes to prove that Solomon was a good deal of a Solomon after all, when he delivered his celebrated dictum, that "there was nothing new under the sun."

Perhaps he meant that there was nothing so new that no suggestion, idea or thought could be brought up concerning it.

* * *

THE new instrument which numerous public prints have noticed as having been invented by one hight Daniel Drawbaugh for use by armies on land, to detect the approach of troops, or at sea the approach of vessels; and heretofore noticed in these columns, consists by the latest accounts "essentially of a microphone and registering dial: the microphone, an extremely sensitive combination of wire is placed in a HOLLOW iron tube, which is hermetically sealed." If this account be correct, we cheerfully accord the credit of novelty to at least one element of the combination.

ARTICLES.

THE PROBABLE DURABILITY OF HARD-DRAWN COPPER TELEGRAPH WIRE.

BY WM. MAVER, JR.

THE extensive use of hard-drawn copper wire as an overhead conductor was begun in this country in the spring of 1884, by the erection of 2,000 miles of that metal (No. 14 B. W. G.) on the lines of the Baltimore and Ohio Telegraph Company, between New York and Chicago, and by the erection of about 600 miles of similar wire between New York and Boston, by a construction company.

At that time successful results from the use of hard-drawn copper wire were considered by many as very problematical. Indeed, several prominent electricians then expressed the belief that the "experiment" would prove disastrous, and one even staked his professional reputation on his prediction to that effect. A number of reasons were given for these unfavorable opinions. Hard-drawn copper wire would not withstand the extreme cold of our northern winters; the intense heat of summer would elongate it; the strain of supporting its own weight would "fatigue" it—or if it escaped these dangers, it would be carried off for "melting purposes" by the light-fingered gentry of the country through which it would pass. By others, its use was looked upon favorably as a very important undertaking, the results of which, if successful, would be of great value to the telegraph and telephone business; those who were interested financially and professionally in the progress of those electrical pursuits very wisely preparing themselves to note and profit by the consequences.

It would be idle to say that the officers of the Baltimore and Ohio company had no doubts whatever as to the outcome of their undertaking; but whatever their misgivings were, it is sufficient evidence of their confidence in the practicability of it that, after thorough investigation of all the difficulties, they recommended and authorized the erection of the 2,000 miles of wire referred to.

The results, however, as is now well known, fully justified their confidence in the undertaking. The summer of 1884 passed without any undue "drawing out," and the cold snaps of the winter of 1884–'85 came and went without damage to the copper wire. Indeed, the reports from the linemen were more encouraging than otherwise, inasmuch as they showed that the percentage of breaks after cold "snaps" was no greater than that of parallel iron wires, More than that, these reports showed that the majority of the breaks of the copper were preventable, having occured at places where the wire had been inadvertently nicked or at improperly made joints. As for losses due to thefts of the copper wire, they were nil, and the table of results of tests given below will show that "fatigue" has not as yet made itself felt.

The knowledge of these facts was easily accessible to any one desiring it; and that they were considered fairly satisfactory may be gathered from the fact, that whilst in January of 1884 there were probably not more than 100 or 200 miles of hard-drawn copper in use in this country, to-day there are, it is estimated, at least 50,000 miles representing about 4,200 tons of metal, now operated by the various telegraph and telephone companies, the average weight per mile being about 170 lbs.

While the officials of the Baltimore and Ohio Telegraph Company felt sufficient confidence in the capacity of hard-drawn copper wire to serve the purpose of an overhead conductor, they realized from the start that it was essential to the success of the undertaking that the utmost care should be exercised both in the manufacture of the wire and in its erection upon the poles. So far as the manufacturers were concerned, it is but fair to say that they fully appreciated this necessity and exerted themselves accordingly, accepting without complaint the rejection of miles of wire for minor defects which to-day, with the knowledge of what margin is allowable, would not raise a question.

On the other hand the telegraph company required the strictest compliance with the rules promulgated for the handling and erection of that class of wire—new methods of making sleeve joints; new or revised ways of tying the wire to the insulator, etc., were adopted, and special pliers were devised and furnished for the making of joints, etc. Particular instructions were given to guard against nicking the copper in any way, the linemen being forbidden to use anything but the hands in handling the wire, the pliers above referred to being employed to hold the sleeve firmly during joint making. The nicking of the wire was soon found to be its weak point, a fact which will be made apparent to any one by drawing the edge of a knife lightly around the circumference of a hard-drawn copper wire, so as to make a mark; on bending the wire it will invariably break clear off at the mark.

Strict attention to every detail in the erection of this wire has ensured successful results, while the unsuccessful results are mostly traceable to neglect of such details, and the handling of the copper wire as linemen are accustomed to handle iron wire.

The predictions of immediate disaster to the users of hard-drawn copper wire having been satisfactorily disposed of, the question as to its probable useful "life" as an overhead telegraph and telephone conductor becomes an important one, and such data as it has been possible to gather at all systematically, in the four years since its introduction on a large scale, will perhaps prove interesting.

During the three and one-half years in which the Baltimore and Ohio Telegraph Company used its 8,000 miles of hard-drawn copper—about equally divided between No. 12 and No. 14 B. W. G.—half yearly tests and inspections were made of it.

With a view of obtaining practical data from which to ascertain the "standing up" qualities of the wire under as many different conditions of temperature and weather as possible, and as to its durability under circumstances that were known to be quickly destructive of iron wire, the specimens from which the tests were made were taken from the lines of that company in the states of New York, Pennsylvania, Ohio, Illinois, Indiana and Arkansas; from the cities and counties, and the vicinity of smelting and coke furnaces.

	5	.104	580	1.4	3½	24	5	.083	345	.8	3	33
	Average	.104	572	1.28	3½	32.8	—	.083	356	.93	3.1	33.6

The chief linemen throughout the service were also instructed to observe closely and report to headquarters any instances of abnormal deterioration of the copper wire as compared with iron wire, and the electricians of the company made periodical personal inspections of the wire for the same general purpose.

The table gives results of mechanical tests of No. 12 and 14 B. W. G. copper wire made before the wire left the factory, and also after nearly four years service. The tests for the year 1884, are samples of many made on behalf of the company by a competent expert. The table for the year 1887, shows actual tests of specimens taken at random from different points of the company's system. All of these mechanical tests were made by the same expert using the same machinery, so they may be considered fairly comparative.

The average of a series of tests for tensile strength of sleeve joints carefully made at headquarters was 545 pounds for No. 12, and 331 pounds for No. 14 B. W. G. copper. The average of a series of similar joints made by the linemen in regular work and taken from the lines after they had been in service from two to three and one-half years was 530 pounds for No. 12, and 320 pounds for No. 14 B. W. G. As already said the foregoing tests do not appear to show any signs of tendency to "fatigue" or weakening of the metal. The tests made after the wire had seen service showing no appreciable loss of strength.

Careful examination of all the specimens, including the latest received from different sections of the country, fail to disclose any signs of deterioriation. Specimens taken from the open country, away from the railroad, are simply tarnished by exposure. Those from cities and the neighborhood of furnaces are coated more or less thickly with a sooty substance easily removable, and measurements of the wire after the removal of the coating by washing show no diminution of the diameter.

Accompanying one specimen of No. 14 wire, erected in June, 1884, and in first-class condition when received in the latter part of 1887, was a note by the superintendent to the effect, that a No. 14 steel telephone wire on the same poles and vicinity, namely, the drill yard of the Chicago and St. Louis Railroad, Cleveland, O., had been completely corroded in one year. The only unfavorable comments received from the chief linemen with regard to the use of copper wire were relative to the No. 14 wire, which some of them considered of too low tensile strength, more especially in wooded country, as in many cases it would give way under the strain of a broken bough falling, which a slightly stronger wire would have upheld until the bough could have been removed. This opinion of No. 14 wire, as regards tensile strength, is now generally entertained by telegraph and telephone people; and it is not likely that wire much lighter than 170 lbs. per mile will be extensively used hereafter.

Careful enquiry among the majority of the most extensive users of hard-drawn copper wire has elicited the information that the foregoing general results have been verified by their experience.

While, therefore, the successful experience of the past four years may not be considered sufficient to justify a definite prediction of the "life" of hard-drawn copper wire, it will doubtless be admitted generally that it is sufficient, in view of the already well known superior durability of copper over iron under ordinary atmospheric conditions, to warrant the prediction that it will incomparably exceed that of iron wire.

But these remarks, it should be understood, refer only to such hard-drawn copper wires as have had the advantage of careful attention during manufacture and erection, without which—experience has already shown—wires would soon stand in need of reconstruction.

It may not be amiss to comment on the probable effect of the recent decided advance in the price of copper, on its further use for telegraph and telephone purposes.

It has been stated in some quarters, in connection with this advanced price, that the superiority of hard-drawn copper over iron for telegraph and telephone purposes is not sufficiently well established to warrant the companies in continuing to purchase it in preference to iron at the existing high figure. The question is an interesting one. There is little doubt that the low price of copper in 1884 played a large part in the extensive adoption of hard-drawn copper wire as an overhead conductor. It is not probable that, in the face of the uncertainty which existed at that time as to its "standing up" qualities, any company would have been inclined to invest capital in that metal if iron wire, whose qualities in that respect were well known, was to be had at a much lower figure. But now that the practical utility, that is the "standing up" quality of hard-drawn copper wire has been satisfactorily demonstrated, it is unlikely that the present artificially advanced price of copper will do more than temporarily retard or limit its use, if it does that.

There are several reasons for this view. In the first place the electrical properties of copper wire are so greatly superior to iron, especially for long-distance telephony, that its continued use for this purpose is almost if not altogether imperative. Its use in telegraphy has certainly been advantageous. Even at the increased price of copper its cost as compared with iron, electrically considered, is about equal if indeed the advantage is not with copper. For instance, a copper wire having a resistance of, say, 4.44 ohms per mile will weigh about 200 pounds, which at 22 cents per pound, cost $44. An iron wire of the same resistance will weigh about 1,100 pounds, and at 4½ cents per pound, cost $49.50. In addition there is the important advantage possessed by copper wire that, when from whatever cause or causes its day of usefulness as an electrical conductor has passed, it still will have a certain intrinsic value as old copper. Whilst old iron telegraph or telephone wire at that stage of its existence known as the "streak of rust" condition, is not worth to any one the expense of removing it from the poles.

Which considerations apparently lead to the conclusion, that unless the copper "trust" forces the price of copper to a point higher than it has as yet seen fit to raise it, that metal will still be more or less extensively employed in the telegraph and telephone service.

CONSTANT CURRENT AND CONSTANT POTENTIAL MOTORS IN PRACTICE.

BY J. A. POWERS.

The field for electric motors in connection with electric lighting plants is being rapidly developed, and the problem as to the proper systems to be used in each locality is becoming a very pressing one. This question must be, to a certain extent, influenced by the individual condition of existing plant and the probable extent and distribution of territory in reference to the location of the central station already constructed.

The time for separate power stations has not yet come, and it seems doubtful if it will, save in exceptional cases, since the cost of skilled labor counts so heavily in the maintenance of both electric light and power stations as to make it advisable to keep the two kindred industries under one management and roof.

This being granted, the question of economic distribution will be a most important one, as the best fields for lighting and power are seldom found together; it is true that the electric motor has released the small manufacturers from the bonds which tied them to the districts where power was to be had; but the power question will not be long confined to the small manufacturer and the large manufacturer. The user of from 10 h. p. up is frequently the owner of his mill or factory or the holder of a long lease. These conditions must determine the choice of a power system, and the corollary to be drawn from this is the question of expense of lines.

Power deals with larger units than light, and means much larger investments for line copper whatever system be employed. Motors of 25 or 50 h. p. will not be uncommon in cities of 50,000 population; but the customer using

the same electrical energy in lighting will always be much more rare, and the average lighting hours will be much shorter than the hours for power. The question of cost of lines becomes, therefore, a very important one.

Constant potential of 110 or 220 volts means a territory restricted to about 2,000 feet from the station, and at this distance a line loss of not less than 10% for any investment within reason for line copper.

These voltages will always be crippled in this range of distribution, and except for large cities will probably not have a wide use for power systems. Each horse-power conveyed 2,000 feet on a line loss of 10% will, with 220 volts potential, involve an investment of about $16 or $18 for copper at 20c. per pound.

The one great advantage of the system is absolute safety in handling. Two hundred and twenty volts gives a shock only disagreeable in its effects. The question of putting out motors on incandescent lighting circuits of this kind has been settled by experience to be not practical to any extent without serious disturbance of the lights. This necessitates the adoption of separate lines where motors of any considerable size are in use.

Constant potential systems of from 400 to 600 volts are the outcome of the heavy expense of lines for the low potential systems. They relieve to some extent the question of line cost, but do so at some expense of personal safety, as every motor carries the full 400 or 600 volts at the brushes, and accidentally touching both poles will cause a heavy shock. The question of danger by grounding while handling the motors also appears as an element of danger. It is doubtful if a voltage of 600 will cause death even with heavy currents, unless the person be predisposed to heart difficulty or some kindred organic trouble; but the point of safety has probably been passed with the 400 unit mark. Considering this to be so, and that 600 volts is the extreme limit of safety for constant potential, with a 10% line loss we can reach a distance of 4,000 feet of $9 to $10 per horse-power for line copper at 20c. per pound. This approaches the reasonable; but a lighter expense would expedite matters in the leasing of large power where the margin of profit is smaller and the item of interest consequently of more importance.

The use of a series system of electric motors has been greatly hindered by the difficulty of obtaining good speed regulation. In the case of constant potential this point solves itself by making the motor with a simple shunt-wound field. The point is so easily achieved as to be generally regarded as a sufficient solution of the whole motor question. That this solution is not a true one many facts in the operation of series motors go to prove.

The question of regulation once economically solved, the question of cost of copper falls to its minimum at once, with the increased voltage.

The fact that more people are killed by constant current or arc circuits than by constant potential, seems by most motor manufacturers and many station operators to be satisfactory proof that they are the most dangerous for all purposes, regardless of the disproportion in the number of such lines and machines in use as compared with high voltage constant potential circuits, and also unmindful of the fact that by far the larger proportion of such accidents are due to bad insulation. That arc machines of high potential are dangerous is not considered to be sufficient cause to prohibit their use in central stations, and, as a matter of fact, machines of 50 to 60 light capacity have the preference in spite of the increase of danger with the increase of potential.

Constant current motor circuits of 10 amperes are the most convenient for existing arc stations. They have the disadvantage of liability to failure from open circuits, which the ordinary wire (No. 6 Brown and Sharpe gauge) is not heavy enough to form an entire safeguard against.

The limit of safety from shock (taken at 400 or 600 volts) is soon reached at about five to six h. p., and the question of insulation forms an important part of the cost of the line if it receives the attention necessary to avoid all possible chances of ground.

The proper remedy for the cure of these defects is to increase the current to say 40 or 60 amperes, when the limit of safety from shock at the brushes is at once advanced to 20 or 30 h. p., while the cost of insulation per h. p. on the line is considerably less. As to the total E. M. F., there is no more reason to restrict the E. M. F. of motor lines than of arc lines on which the limit is about 2,000 to 2,500 volts. The first cost of the copper on such lines is not over one-fifth that of constant current lines of 400 to 600 volts for equal distances, which will allow the best of insulation being employed and still leave a wide margin of savings.

The danger of open circuits from rupture of lines would be much reduced, and the wire, No. 2 to 4 B. & S., would be as heavy as can be conveniently handled when heavily insulated.

The one necessary point for safety is to place the motor out of reach of ground connection. A cut-out of much heavier and larger construction than for arc lighting would be required to disconnect the line when not in use.

A year's experience in the operation of arc motors has confirmed opinions previously formed of the freedom from burning out of armatures. With an average of about 25 motors in use, two cases of burned armatures have occurred, both from grounding on the iron core, neither being from overheating. One of these cases occurred within a few hours of starting the motor, and was due to bad insulation.

Much has been said of the lack of efficiency of series motors under light loads. Recent tests on motors of one-half and one h. p. show, with 10 amperes of current in the line, 21 per cent. of the E. M. F. under full load when the motor was running light without the belt. The average E. M. F. in use was about 50 per cent. to 60 per cent. of the full E. M. F. required to develop the rated power of the motor. This is very satisfactory in a financial point of view. The readings were limited to one-half and one h. p. motors by the range of the voltmeter used, which was a Thompson-Rice, rated only to 150 volts.

The proof of the pudding is, after all, in the eating, and that after running a single motor for nearly six months to test its durability, there were obtained in the following six months orders for 90 h. p. of series motors, best illustrates the fact of their satisfactory performance.

One point of great economic value shows up sharply in using series instead of shunt motors. The customer cannot use more than the rated power of the motor unless the speed is increased. This is, of course, easily detected. When the motor is overloaded it simply slows down, and as this is precisely what the small steam engine does under like circumstances, it presents no objection to the average user of power, who would otherwise load his motor as long as it would carry load, and in the case of a shunt motor would insist that his motor was not overloaded "because it did not slow down any."

A recent case came to the notice of the writer of a 10 h. p. constant potential motor which rented for $700 per year, and which the ammeter showed was doing 18 h. p. of work.

It is believed that when the advantages of series motors become more fully known they will have the preference in such miscellaneous work as is called for in central stations practice. They are certainly not so liable to cause such dangerous shocks as high voltage constant potential systems by contact across the poles, as the maximum potential on the largest motor should never exceed that in use on high constant potential systems, while with the smaller motors, which are presumably handled by a more careless and ignorant class of people, the potential across the brushes hardly exceeds that of the multiple arc motor of low potentials. The one danger, as before stated, is from

carelessness in locating the motor within reach of ground connections. The cure for this is like the well-known remedy for the cure of hens which eat their eggs, viz., cutting their tails off close behind their ears, and buying new hens. See that the motors are carefully installed, use the best insulation money can buy, put it up with care, and there will result a motor plant, safer to handle, cheaper to install, cheaper to run, and cheaper to maintain, than any multiple arc system of either high or low potential.

FORMULÆ FOR TRANSFORMERS.[1]

BY PROFESSOR GEORGE FORBES, F.R.S. (L. AND E.).

THE modern transformer for electric lighting is an induction apparatus in which the primary coil is of high, and the secondary of low, resistance, consisting of two ring coils of insulated copper wire enclosed in an iron sheathing, so subdivided as to prevent the formation of local currents in the iron when subjected to the influence of alternating electric currents in the coils. The terminals of the primary are kept at a constant mean difference of potential. The secondary circuit includes the lamp circuit, and is of varying resistance. The iron is so situated with respect to the coils that there is no free magnetism; this simplifies the mathematical treatment of the phenomena.

It is required to predict (1) the magnetic induction in the iron, (2) the work given off to the lamp circuit, (3) the whole work absorbed by the apparatus, (4) the waste of energy when no lamps are in circuit, and (5) the effect which will ensue from varying the construction of the apparatus. The first of these has been approximately solved on the assumption that the permeability of the iron is constant.[2]

It is generally assumed that in such a system of electrical distribution the electromotive forces, the electric currents, and the magnetic induction are simple harmonic functions of the time. This would not be the case if the phenomenon called by Ewing "magnetic hysteresis" is taken into account, and in a preliminary investigation this must be omitted. Its effect in practice is insignificant so long as the magnetic induction in the iron is not high.

The notation now adopted is as follows:—

p_1 = number of turns in the primary coil.
p_2 = " " " secondary coil.
r_1 = resistance of the primary coil.
r_2 = " " secondary circuit, including lamps.
c_1 = current in the primary circuit.
c_2 = " " secondary circuit.
m = integral of the induction over the cross-sectional area of the iron.
$\rho = \dfrac{\text{mean length of lines of induction in the iron.}}{\text{cross-sectional area of iron} \times \text{permeability.}}$
$n = \pi \times$ number of alternations of E. M. F. per second;
$= 2\pi \times$ " " complete periods of E. M. F. per second.
w_1 = work done in unit time by the primary current.
w_2 = " " " in the secondary circuit.
e = difference of potential of primary terminals.

C. G. S. units are adopted throughout.

Assume
$$m = \mathrm{M} \sin n t \quad . \quad . \quad . \quad . \quad . \quad (1)$$

then
$$c_2 = -\frac{p_2 d m}{r_2 d t} = -\mathrm{M}\, n \frac{p_2}{r_2} \cos n t \quad . \quad . \quad (2)$$

and
$$w^2 = \int_0^1 c_2^2 r_2 dt = \frac{\mathrm{M}^2 n^2 p_2^2}{r_2} \int_0^1 \cos^2 nt = \frac{\mathrm{M}^2 n^2 p_2^2}{2 r_2} \int_0^1 (1 - \cos 2nt) dt.$$

The mean value of the periodical part is zero. Hence
$$w_2 = \frac{\mathrm{M}^2 n^2 p_2^2}{2 r_2} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Again,
$$\mathrm{M} \sin n t = \frac{4\pi}{\rho} (p_1 c_1 + p_2 c_2);$$

whence
$$c_1 = \frac{\mathrm{M}\rho}{4\pi p_1} \sin n t + \frac{p_2^2 n \mathrm{M}}{p_1 r_2} \cos n t \quad . \quad . \quad (4)$$
$$= \mathrm{C}_1 \sin (n t + a),$$

if
$$\mathrm{C}_1 \cos a = \frac{\mathrm{M}\rho}{4\pi p_1} \text{ and } \mathrm{C}_1 \sin a = \frac{\mathrm{M} p_2^2 n}{p_1 r_2}.$$

Again,
$$c_1 = \frac{\mathrm{E}}{r_1} \sin (n t + \beta) - \frac{p_1}{r_1} \frac{dm}{dt}; \text{ if } e = \mathrm{E} \sin (n t + \beta),$$
$$= \frac{\mathrm{E}}{r_1} \cos \beta \sin n t + \left(\frac{\mathrm{E}}{r_1} \sin \beta - \frac{p_1 \mathrm{M} n}{r_1}\right) \cos n t \quad . \quad (5)$$

Equating coefficients in (4) and (5), we have
$$\mathrm{E} \cos \beta = \frac{\mathrm{M}\rho r_1}{4\pi p_1}; \; \mathrm{E} \sin \beta = \mathrm{M} n \left(p_1 + \frac{p_2^2 r_1}{p_1 r_2}\right)$$
$$= \mathrm{M} n p_1 \left(1 + \frac{p_2^2 r_1}{p_1^2 r_2}\right);$$

whence
$$\frac{\mathrm{E}^2}{\mathrm{M}^2} = \left(\frac{\rho r_1}{4\pi p_1}\right)^2 + n^2 p_1^2 \left(1 + \frac{p_2^2 r_1}{p_1^2 r_2}\right)^2 \quad . \quad (6)$$

also,
$$w_1 = \int_0^1 c_1 e\, d t = \mathrm{C}_1 \mathrm{E} \int_0^1 \sin (nt + a) . \sin (nt + \beta) . dt$$
$$= \frac{\mathrm{C}_1 \mathrm{E}}{2} \int_0^1 \{\cos (a = \beta) - \cos (2 n t + \beta + a)\} d t$$
$$= \frac{\mathrm{C}_1 \mathrm{E}}{2} \cos (a - \beta) = \frac{\mathrm{C}_1 \mathrm{E}}{2} (\cos a \cos \beta + \sin a \sin \beta)$$
$$= \frac{\mathrm{M}^2}{2} \left\{ r_1 \left(\frac{\rho}{4\pi p_1}\right)^2 + \frac{n^2 p_2^2}{r_2} \left(1 + \frac{p_2^2 r_1}{p_1^2 r_2}\right) \right\} \quad . \quad . \quad (7)$$
$$= \frac{\mathrm{E}^2}{2} \cdot \frac{r_1 \left(\frac{\rho}{4\pi p_1}\right)^2 + \frac{n^2 p_2^2}{r_2} \left(1 + \frac{p_2^2 r_1}{p_1^2 r_2}\right)}{\left(\frac{\rho r_1}{4\pi p_1}\right)^2 + n^2 p_1^2 \left(1 + \frac{p_2^2 r_1}{p_1^2 r_2}\right)} \quad . \quad . \quad (8)$$

When the actual figures pertaining to a modern transformer are inserted, it is found that the quantity $\frac{p_2^2 r^1}{p_1^2 r_2}$ is less than .01; that the first term of the numerator in (8) is small compared with the second; and that the first term of the denominator is very small compared with the second.

The efficiency is found by dividing (3) by (7).

When no lamps are used on the secondary circuit, the rate of work done is, by (7) (r_2 being infinite),
$$\text{waste} = \frac{\mathrm{M}^2}{2} r_1 \left(\frac{\rho}{4\pi p_1}\right)^2.$$

It will be noticed that the efficiency of the apparatus depends on the first term in (7) being small compared with the second; hence n (or the number of alternations per second) may be diminished without loss of efficiency if ρ be diminished, or if the mass of iron be increased.

WHY PROFITS DWINDLE.

BY D. C. JACKSON.

IN the struggle between cheapness and economy in electric light plants, it is surprising that economy is so frequently permitted to go to the wall.

Many of the plants erected in the eastern portion of the country during the last three years show that the investors have partially learned the advantages of plants in which there is to be found only thoroughly first-class workmanship. In a few plants careful attention has been given to the designing and construction of every part of the system, from the setting of the boiler, where the heat energy is first gathered from the coal, to the filament of the lamp, where this energy undergoes its final useful transformation. The performance of such plants has thoroughly proved the economy of first-class construction.

In the west, where coal and supplies are particularly costly, while money commands a large return in legitimate business channels, it would seem rational to expect the question of economy to receive the earliest consideration. In order to make electric lighting pay to western capital a fair return, the highest perfection of mechanical and electrical details must be observed; still, under these conditions, cheapness holds almost undisputed sway. This is in part, no doubt, due to the general hurry for improvements in the west; but there are more potent causes, not to the credit of the parent companies who have erected the plants.

The writer can name a number of plants in towns of 2,500 to 50,000 inhabitants, located between the Mississippi River and the Rocky Mountains, some of which are paying no dividends on their stock, others that are giving a fair return. All of these would readily have paid, with their present receipts, a percentage dividend ¼ or ½ greater on the slightly increased capital required, if the plants had been put in on an economical basis, making them gilt-edged in the eyes of the engineer and truly gilt-edged for the investor.

Some of the faults to be observed in plants now working, are due to the installation of a system entirely unsuited for the work required; some are in electrical details and line construction, causing the cost for repairs to consume all profits. Others are to be found in the steam plants, the voracious coal eating of which causes the receipts to slip between the fingers of the stockholders into the pockets of the coal dealers. Where the cheapest slack coal costs $3.75 per ton, a cheap boiler, poorly set, and an engine consuming 20 lbs. of coal per horse-power per hour, should find no place in an electric light plant; but the writer is well acquainted with a small incandescent plant running under exactly such conditions in a town of 3,000 people. It is truly surprising that this plant earns a fairly good dividend.

There are arc plants, the line wire of which is composed of all sizes from No. 7 to No. 4 spliced together, and in which the poles will soon be flat on the ground, on account of their shallow setting; others where half the lights go out on every damp night, because of poor insulation.

In multiple series systems are found incandescent lamps that have been made for use on constant potential circuits, where, let us hope, they would be uniform; but when placed in a group, all of which must receive the same current, lamps of normally 16 c. p. vary amongst themselves from 12 to 25 candles.

In one plant that has fallen under the writer's observation, the poles average about 40 feet in height, and originally were nearly all composed of short poles spliced together in the most slovenly manner. It is needless to say that under the stress of a number of large wires some of these poles threatened to collapse, making it necessary to replace them out of the receipts of the local company. Another case of bad line construction needs no comment here. Three guy stubs are placed in a row to hold one corner pole. The pole was 40 feet high and the first stub set was thirty feet long with a very small top and a splice in the middle. The splice broke, and another stub was set 50 feet back of the first to hold it up. This in turn was set too shallow, and was in a fair way to be pulled out of the ground, when a short stub was placed back of it to hold it down. It may be well that the western people care more for utility than beauty; but such a disfiguration of the streets with poles is carrying the matter a little too far.

These examples are but a few of many that can be put in evidence to show the grossly bad construction put in by the "experts" of some of the largest parent companies.

When under competition in a place where there is no fear of the insurance inspector, the companies apparently vie with each other as to which can erect the cheapest and most unsubstantial plant. The item of profit to the local companies is too insignificant for consideration.

Under such treatment, economy is necessarily lost; and electric lighting naturally loses favor with the investors. There is abundant proof that, where properly installed and well managed, an electric light plant will always produce large dividends on invested capital. That so many plants are losing money is due chiefly to the culpable management of the parent companies, through their agencies, aided by the impression of the public that all things electrical must be *good* without gradation of quality.

LINCOLN, Neb., March 13, 1888.

ON ALTERNATE CURRENT TRANSFORMERS, WITH SPECIAL REFERENCE TO THE BEST PROPORTION BETWEEN IRON AND COPPER.[1]

BY GISBERT KAPP.

THE principle on which all induction coils, and therefore all the different forms of alternate current transformers, depend is that of a magnetic circuit interlacing with an electric circuit. In its simplest form this relation can be represented by two rings threaded through each other, figure 1, one representing the electric circuit and the other the magnetic circuit. Modern transformers have all a closed core, so as to compel, as far as possible, all the lines of the magnetic circuit to pass through the electric circuit, which consists of a primary and secondary coil; but they differ from each other in the particular manner in which the circuits are arranged, with a view to attain the following objects: reduction of the length of the two circuits, reduction of the weight of materials employed, ventilation, facility of manufacture and repair, efficiency of insulation, and reduction of cost of manufacture. Omitting for the present those considerations which more nearly concern the practical manufacture, we may divide transformers broadly into two classes—one in which the copper coils are spread over the surface of the iron core, enveloping the latter more or less completely; and the other in which the core is spread over the surface of the copper coils, forming a shell over the winding. I propose to call the former "core transformers," and the latter "shell transformers." A familiar example of the first class is the armature of an ordinary Gramme dynamo, while the particular type of transformer introduced by Mr. Zipernowski may serve to illustrate the second class. They are represented in the diagrams figures 2 and 3. It is evident without mathematical investigation that, whatever may be the proportion between the external and internal diameter of the ring, the electric circuit must be shorter than the magnetic circuit in the Gramme ring or core transformer, while the opposite must be the case in the Zipernowski ring or shell transformer. When, a few years ago, this type was introduced, it was, on account of its short magnetic circuit, generally believed to be an immense improvement upon the Gramme ring; and I have heard it stated that with the Zipernowski outside core absolute perfection has been reached, since "every inch of copper wire contributes to produce electromotive force." I propose presently to lay before you a short investigation into the relative merits of the Gramme and Zipernowski rings, and also into the best proportion of copper to iron in either; but before entering into this subject I would submit a few theoretical considerations, so as to obtain a basis for this investigation.

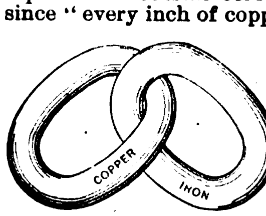

FIG. 1.

Since the electromotive force developed in the secondary circuit is proportional to the co-efficient of mutual induction between that and the primary circuit, and since self-induction tends to produce lag and so reduce the output of the apparatus, it is obviously advantageous, both for efficiency and output, to so arrange the coils that their co-efficient of mutual induction should be a maximum for the given co-efficients of self-induction in the primary and secondary circuit. According to a well-known law, the maximum value which the co-efficient of mutual induction can have is equal to the square root of the product of the two co-efficients of self-induction; and the necessary and sufficient condition for obtaining this maximum is that the same number of magnetic lines of force should pass through both circuits. In other words, the whole of the flow of force should take place within the core, and no free poles should be formed. This condition can easily be fulfilled by a suitable arrangement of the two circuits in close proximity, and, as a matter of fact, is fulfilled in all modern transformers. We shall, therefore, assume that the same flow (F) of magnetic lines of force passes through both circuits, and that the electromotive forces produced in the two circuits bear to each other the same proportion as their respective

1. Read before the Society of Telegraph Engineers and Electricians, February 9, 1888.

number of turns. We shall further assume that the electromotive force impressed on the terminals of the primary coil, or the current sent through it, is a simple sine function of the time—in other words, that the electromotive force developed in the armature of the dynamo is such a function. Whether the latter condition is generally fulfilled by modern machines I am unable to say; but I believe that the presence of a transformer in the circuit has the tendency to smooth down any deviations from a true sine curve should they occur in the armature, and, further, that a curve of E. M. F., of whatever shape, produced by a machine will, after filtering through two or three transformers, come out as a true sine curve. It would be of value if some one having the necessary mathematical attainments would investigate this point; but for our present purpose it is sufficient to assume that the electromotive force produced by the machine follows with fair approximation a simple sine function, and that the deviations are unimportant. This assumption has up to the present been made by all who have investigated the subject of transformers.

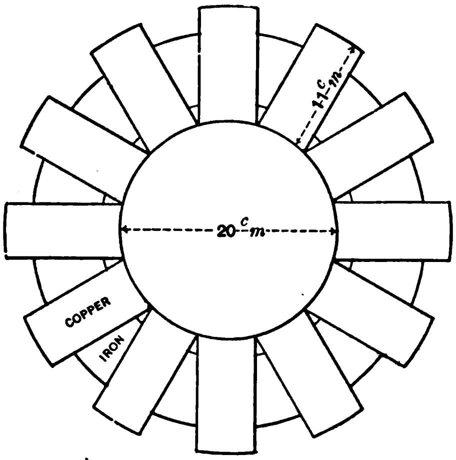

FIG. 2.

Let, in the following:

n represent the number of complete cycles performed per second;
F " " flow of force in C. G. S. lines;
B " " maximum inductions (crest of wave);
τ " " number of turns in the coils, the indices 1 and 2 being used to distinguish the primary from the secondary coil;
E " " maximum electromotive forces (crest of wave) in volts, the indices 1 and 2 being used to distinguish the primary from the secondary coil;

$e = \frac{\sqrt{E}}{2}$ represent the average electromotive forces;

I represent the maximum currents;

$i = \frac{\sqrt{I}}{2}$ represent the average currents;

L represent the length of the magnetic circuit in centimeters;
a " " area of core available for the flow of lines in square centimeters.

$R = \frac{L}{a}$ represent the magnetic resistance of the core;

μ represent its permeability;
r " the electric resistances;

then we have the following well-known relations:

$$B = \frac{F}{a}; = \frac{\mu\, 4\, \pi\, \tau\, I\, 10^{-1}}{R}; E = 2\, \pi\, n\, F\, \tau\, 10^{8}; \frac{E_1}{E_2} = \frac{\tau_1}{\tau_2}.$$

Calling e'_1 and e'_2 the average electromotive forces at the primary and secondary terminals respectively,

$$e'_1 = e_1 + r_1\, i_1;\ e'_2 = e_2 - r_2\, i_2.$$

When a transformer is at work we have the following phenomena:

1. A wave of impressed primary electromotive force.
2. A wave of counter electromotive force in the primary coil, but not exactly coinciding with the impressed.
3. A wave of primary current not coinciding with either.
4. A wave of magnetization lagging behind the primary current wave by something less than a quarter period.
5. A wave of electromotive force in the secondary coil lagging behind the magnetization wave by a quarter period.
6. A wave of secondary current, coinciding with the former (5) in period if the external circuit contain no self-induction—a condition approximately fulfilled where the current is only used for lighting glow lamps.

The problem now is to find what relations exist between these different waves as regards their relative positions and magnitudes. At first sight it may seem that this would prove a very difficult problem; and if an algebraic solution be attempted it is, in fact, if not very difficult, at least enormously complicated; but it is easy to treat the matter geometrically in a very simple way. As this method has already been published some time ago, it will not be necessary to demonstrate it, and I shall limit myself to a brief description, pointing out a modification of the original method by which the energy dissipated in magnetizing the core can be taken into account. It will be seen from the above equations that F and E are proportional. Consequently, if we know what E. M. F. is to be put on the primary terminals of a given transformer, we also know with very close approximation what the induction and total flow of lines will be. If it were not for the slight disturbing influence of the resistance of the primary coil, we would know these data exactly. But the loss of E. M. F. by resistance can, for obvious reasons, only be trifling, and will in most cases be settled beforehand. We can therefore determine F with perfect accuracy, and from the constructive data of the core also the exciting power ($\tau\, I$) which will produce this flow. It will be shown presently that it is inexpedient and uneconomical to work transformers with a high induction, and we may therefore regard the permeability to be constant for all points in the cycle. In this case $\tau\, I$ and F, must at all times be proportional. Let, in figure 4, the circle represent the effective exciting power which we assume to coincide with the magnetization, so that the projection on the vertical of the radius $O\, P$, as it revolves (clockwise) round O, represents the effective exciting power in ampere turns, and, to a different scale, also the flow of force at any instant. The line representing the current in the secondary must evidently lag behind $O\, P$, by a quarter cycle, and can be calculated from the formula for E_2, and from the resistance of this circuit. This gives us $O\, I_2$, the maximum exciting power due to the secondary coil alone. By erecting a vertical on $O\, P$ in P, and making $P\, I_1 = O\, I_2$, we find the line $O\, I_1$, which represents in position and magnitude the maximum exciting power due to the primary coil alone. This gives us also the primary current, and we can now determine the loss of electromotive force due to the resistance of the primary coil. Let $O\, R_1$ represent this in direction and magnitude. The counter electromotive force in the primary must evidently be in advance by a quarter period over the magnetization; that is to say, it must be represented by a certain length on the line $O\, Y$. Its amount can be calculated from the formula for E_1. Let $O\, E_1$ represent it to the same scale as was used for $O\, R_1$; then the parallelogram $O\, R_1\, Et_1\, E_1$ gives us at once the point Et_1 and line $O\, Et_1$, which represents in position and magnitude the maximum electromotive force impressed on the terminals of the primary

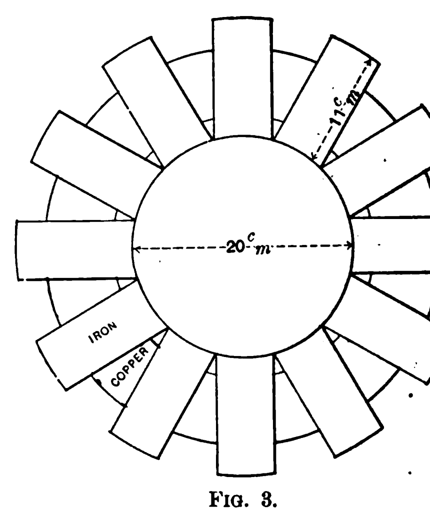

FIG. 3.

coil, and α is the angle of lag of current behind the impressed E. M. F. The work done on the primary coil is found by the well-known formula:

$$W_1 = \frac{I_1\ Et_1}{2} \cos.\ \alpha;$$

$$W_1 = i\ et_1 \cos.\ \alpha.$$

That is to say, the true work is equal to the product of the apparent work, as measured by a dynamometer and voltmeter and the cosine of the angle of lag. If the apparatus were supplied with current at a constant and undirected E. M. F. the apparent and the true work would be equal, and the ratio $\frac{1}{\cos.\ \alpha}$ indicates how much larger must be the capacity of an alternate-current plant to do the same true work as a continuous-current plant. I propose, therefore, to call cos. α the "plant efficiency" of the transformer.

It was stated above that transformers should be worked at a comparatively low induction. This might seem at first sight a retrograde step, since with dynamo machines considerable gain in efficiency and output has resulted from adopting an induction up to 20,000 and more, but by reference to figure 4, one of the reasons why a low induction is preferable will be at once apparent. Suppose that the line $O\ P$, represents the limit to which the induction

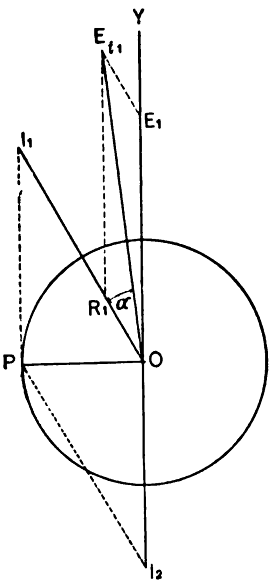

FIG. 4.

may be put without diminishing the permeability: then if the same transformer be worked at double the electromotive force, we would require an exciting power not only twice, but many times as great as previously. This would bring the point P, considerably to the left without increasing the length of the line $P\,I_1$. It would also increase the length of the line $O\ I_1$—that is, the primary current—and therefore the heat generated in the primary coil, whilst the angle of lag would become greater and the plant efficiency smaller. Similar results would follow from an increase in the magnetic resistance of the core, or from the omission of core altogether. An early type of transformer made by Messrs. Gaulard & Gibbs had no iron core, and therefore no well-defined magnetic circuit; but as the primary spirals alternated with the secondary spirals our previous assumption regarding the coefficient of mutual induction remains valid, and the above formulæ and graphic method could be applied to this apparatus if we knew what value to assume for the resistance of the magnetic field. This, however, we do not know; but the case is of no importance at present, as transformers without iron cores have become obsolete. I only mention this early apparatus because the experimental investigations of Dr. Hopkinson and Professor Ferraris[1] have proved that there is a considerable difference between the apparent and the true work; that is to say, the point P, must have been a considerable distance to the left, making the plant efficiency small In modern transformers the point P, lies so close to O, that the plant efficiency may reach as high as 99 per cent., so that the difference between real and apparent work supplied to the apparatus when giving full output becomes trifling; and for a practical determination of efficiency the readings of measuring instruments on the primary and secondary circuit may be used, with only such corrections as may be applied from the diagram.

A high plant efficiency is, however, not the only reason why transformers should be worked at a low induction. A far more important reason is the heating which takes place in the iron of the core if this be carried rapidly through cycles of intense magnetization. This heating is not due to eddy currents (although these currents in a badly designed core would produce the same effect), but seems to be the result of what may be termed dissipation of energy by molecular friction or hysteresis. The energy dissipated per cycle per cubic centimeter increases in more than simple ratio with the induction, and it seems also to increase as the periodic time decreases. As yet very few experiments have been made to determine the hysteresis for different samples of iron, the most important data published being those given by Professor Ewing and Dr Hopkinson in the *Philosophical Transactions*, part ii., 1885. Professor Ewing distinguishes between static hysteresis (slow period) and viscous hysteresis (quick period), but the experimental data refer only to the former. According to Dr. Hopkinson, the energy required to carry one cubic cenmiteter of annealed wrought iron through a complete cycle of induction equal to 18,251 lines is 13,356 ergs, and for hardened tungsten steel with an induction of 14,480 lines the energy reaches 216,864 ergs. Professor Ewing found that with very soft annealed wrought iron and $B = 13,190$, the energy dissipated by hysteresis was 9,300 ergs. He also tested annealed iron wire by carrying it through lower cycles; and, as the results are of very great importance in the construction of transformers, they are given herewith:

Induction.	Energy.	Induction.	Energy.
1,974	410	10,590	5,560
3,830	1,160	11,480	6,160
5,950	2,190	11,960	6,590
7,180	2,940	13,700	8,690
8,790	3,990	15,560	10,040

These figures refer to static hysteresis. As regards viscous hysteresis, no experiments have been made; but in the case of $B = 8,500$ and $n = 80$, Professor Ewing estimates the energy dissipated per cycle at 5,000 ergs. or 32 per cent. above that of static hysteresis. When applying the figures of the table to transformers it may therefore (until further experiments have been made) be advisable to add from 30 to 40 per cent. to the energy there given. Thus, if an induction of 18,000 be adopted, the energy dissipated would amount to 18,000 ergs per cubic centimeter per cycle; and with 80 cycles per second this corresponds to .144 watt per cubic centimeter of core. It would evidently be extremely difficult, if not altogether impossible, to provide cooling surface enough for this rapid generation of heat, and hence it is necessary to work at a lower induction, the exact amount to be determined for each transformer by the cooling surface of the core and coils, and by the heat generated in the coils themselves. So far, then, theory points to the necessity of low induction. As regards practice, I believe the makers of transformers have already found out that it does not pay to press the iron magnetically too hard. My own experience was at least in this direction. In the first transformer which I designed jointly with Mr. W. H. Snell, and which is on the table, we worked at an induction of 20,000, and there were produced two very undesirable results. In the first place, the core heated to such a degree that continuous work was out of the question; and, in the second place, the apparatus emitted a most unmusical sound, and it was evident that on this account alone it was not fit for practical use. The sound may have been partly due to the employment of wood for the framework, but we believed that the high induction was principally the cause, and by

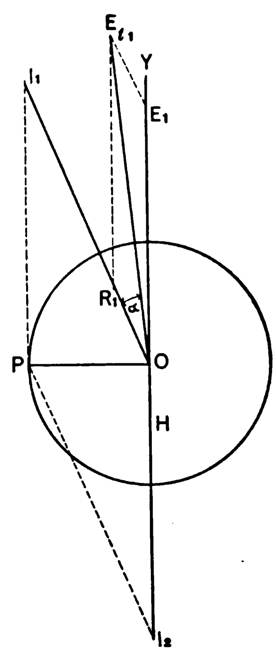

FIG. 5.

dropping the E. M. F. so as to get an induction of 15,000 we found that these evils were lessened. We then constructed another transformer, in which the induction was reduced to 10,000. This transformer is also on the table. In it the sound was suppressed, but the temperature still rose by about 30° C. when continuously at work. We have therefore, in a later design, adopted a still lower induction. Although it is possible to reduce in this manner the amount of energy dissipated in the core, this waste cannot be entirely prevented, and must therefore be taken into account when determining by the aid of the diagram the working conditions of the apparatus. For this purpose it would, strictly speaking, be necessary to know, in addition to the total energy dissipated per complete cycle, also the rate of dissipation at each point of the cycle—a knowledge which we do not possess. It

1. "Ricerche Theoriche e Sperimentali sul Generator Secondario Gaulard e Gibbs," by Galileo Ferraris. Turin, 1885.

seems, however, reasonable to assume that the rate of dissipation of energy by hysteresis follows the same law as the rate of dissipation of energy due to eddy currents—that is to say, that it is proportional to the rate of change of induction. When the induction passes through zero the rate at which the heat is generated would be a maximum, and this would gradually diminish to zero as the induction approaches its positive or negative maximum. On this assumption we can imagine eddy currents substituted for hysteresis; and in an iron core perfectly devoid of the latter property—that is, infinitely soft—the same amount of heating could be produced by imperfect subdivision, or better still, by subdividing it perfectly, but wrapping around it a closed conductor of such a resistance that the heat generated in this

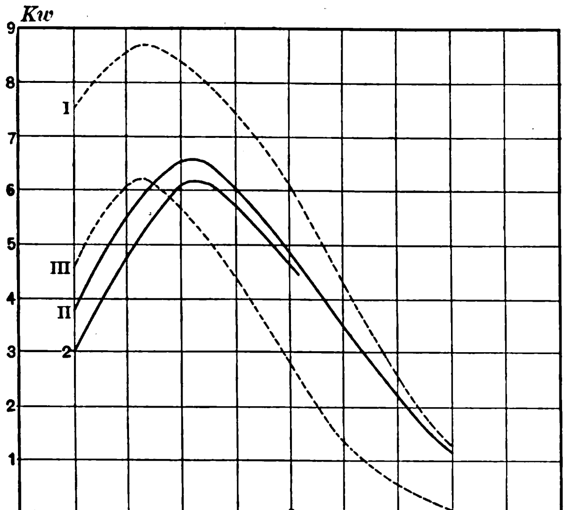

FIG. 6

conductor equals that dissipated by hysteresis in ordinary iron. For the ordinary transformer consisting of an imperfectly subdivided core of iron not infinitely soft and a primary and secondary coil, we would substitute an imaginary transformer consisting of a perfectly subdivided core of iron free from hysteresis, a primary coil, a secondary coil, and a third closed coil of suitable resistance. The current in this third coil would coincide with that in the secondary coil, and its exciting power would be added to that of the secondary coil. For example, let the volume of iron affected by hysteresis in a particular transformer be 1,000 cubic centimeters, and let the energy of hysteresis be 5,000 ergs, the total energy dissipated would, with 80 cycles per second; amount to 40 watts. If the electromotive force produced in the secondary coil be 100 volts, then our imaginary third coil would have either the same number of turns as the secondary coil and a resistance of 250 ohms, or it might have half the number of turns and a resistance of 62.5 ohms, or any other combination giving the same loss of energy. The mean value of the fictitious exciting power would in all cases be the same, namely, the number of turns in the secondary coil multiplied by .4 ampere. Let, in figure 5, $O\ H$ represent the maximum value of this exciting power due to hysteresis; then the total exciting power tending to demagnetize the core, and which must in a certain measure be balanced by the exciting power of the primary coil, is represented by the length $O\ I_2$—being the sum of $O\ H$ and $H\ I_2$, where $H\ I_2$ equals $O\ I_2$ of figure 4—and the point I_1 will be pushed higher up as compared with figure 4. The net result of this alteration is an increase in the amount of energy which must be supplied to the primary coil. It is thus possible to include the effect of hysteresis in the geometrical method of representing the working conditions of a transformer. I have dwelt at some length on this question because, notwithstanding its apparently somewhat abstruse character, it is really of very great practical importance. In some transformers the heat generated in the iron core is in excess of that generated in the copper coils, even at full output. Now where transformers are placed in parallel between high potential mains, it is, for obvious reasons of safety, not advisable to allow customers to handle a switch on the primary circuit, and the current must therefore be on, whether lamps are being lighted from the secondary or not. When the supply is continuous, as it obviously must be in a general system, the cyclic changes of magnetism in the core of every transformer will be kept up day and night, and the question of heating becomes of far greater importance than is the case in dynamo machines; which, as a rule, are only worked for a certain number of hours per day.

On the basis of the foregoing we can now investigate the relative merits of the Gramme and Zipernowski rings, and the best proportion of copper to iron in each. I have selected the two original types and one modification of each as being fair representatives of the two large classes into which, in the beginning of this paper, I have divided all transformers. These "rings" are both equally difficult to manufacture, and contain serious practical defects; but from a purely electrical point of view they are probably as good as the majority of transformers now in the market. Their practical defects constitute for my purpose a positive advantage, because nobody will care to claim either as his special type, and I shall thus escape the somewhat invidious task of having to compare the actual transformers made by rival manufacturers. As it is obviously impossible to conduct an investigation of this kind on absolutely general lines, it was necessary to assume rings of definite dimensions. I have selected rings of circular section having an internal diameter of 20 cm. and an external diameter of 42 cm., shown in full size in the wall diagrams (figures 2 and 3). The mean primary potential is assumed to be 2,000 volts, and the secondary 100 volts. The copper coils in figure 2 and the coils forming the iron shell in figure 3 are supposed to touch each other on the inside, and being of equal depth all round, to separate on the outside, exposing part of the inner ring. In the Zipernowski transformer as actually made, the inner diameter of the ring is rather smaller than shown in figure 3, and the shell winding covers the whole surface of the conductors, being of less depth on the outside than on the inside; but the magnetic resistance is in either case so low that the difference between the assumed and actual arrangement does not materially affect the result, whilst the calculations for the former are somewhat less complicated. The total space occupied by insulation I have assumed to be 1 cm. or 2.5 mm. between the core of the Gramme ring and the primary coil, and 2.5 mm. between that and the secondary coil. The same space has been allowed for the Zipernowski ring. We can now assume different sectional diameters for the inner ring (core or coils), and depth of winding for the covering (coils or shell), so as to make up the 11 cm. sectional diameter of the whole ring; and determine the output for each combination so that for continuous work the apparatus should keep moderately cool. From analogy with dynamos I estimate the total energy which may be wasted without producing overheating at 260 watts; and the output has in all cases been calculated on this basis for an induction of 8,500, a periodic time of $\frac{1}{80}$ second, and hysteresis at 5,000 ergs. As it would serve no useful purpose to burden this paper with a reproduction of the somewhat lengthy calculations, I have plotted the results in the curves II, figures 6 and 7. The curves I show the output which might be obtained if hysteresis did not exist, in which case the whole of the 260 watts would be transformed into heat within the coils. The thickness of copper winding, figure 6, and that of the iron shell, figure 7, is plotted on the horizontal; the output on the vertical. From figure 6 it will be seen that the maximum output with the Gramme ring is 6,400 watts with a

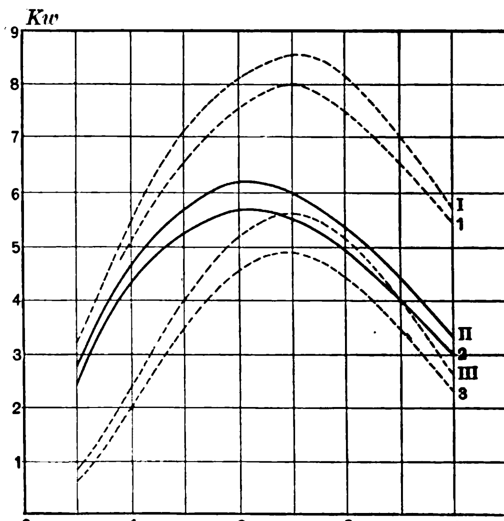

FIG. 7.

thickness of copper winding of about 1.7 cm., leaving 6.6 cm. for the sectional diameter of the core. The cross-sectional area of the magnetic circuit is in this case about 80 per cent. of the cross-sectional area of the electric circuit, and the gross volume occupied by iron is about equal to the gross volume occupied by copper. The maximum output for the Zipernowski ring (figure 7) is 6,100 watts for an iron shell 2 cm. thick, leaving the sectional diameter of the coils 6 cm. The cross-sectional area of the magnetic circuit is in this case nearly eight times that of the electric circuit, and the gross volume occupied by iron is 1¼ times that occupied by copper. Thus with the same external dimensions, the Zipernowski ring gives a slightly lower output than the Gramme ring; but it must be remembered that the weight of copper is also slightly smaller. I have made the same calculation for oblong rings, as shown in figure 8. Imagine the Gramme ring

cut in halves, these straightened and laid side by side, and the two cores joined by semicircular pieces at the ends. The copper coils will in this process not be altered, but the length of the magnetic circuit and the volume of iron in the core will be increased; hence more energy will be absorbed in hysteresis, and the output will be reduced. In figure 6 the curve 2 represents the output for the oblong Gramme ring. By adopting the oblong shape for the Zipernowski ring we do not alter the mass of iron in the shell, but we lengthen the electric circuit, and increase the waste of energy in the coils. In this case also the curve of output 2 (figure 7) must lie below that of the circular type. Curve 1 (figure 7) shows the output of the oblong type if there were no hysteresis. In figure 6 this must obviously coincide with curve I. The maximum output of the oblong type is—for the Gramme ring, a little over 6,000 watts; and for the Zipernowski ring, 5,800 watts.

Up to the present we have only considered the output as limited by the amount of energy which may be wasted without overheating. But there is another an equally important consideration which affects the output, namely, the question of self-regulation. It is evident that in a transformer fed at a constant potential the induction is a maximum when the secondary circuit is open; for in this case the counter electromotive force of the primary is very nearly equal to the electromotive force at the terminals. At full work the two differ by the amount lost in resistance, and the induction is reduced in the same proportion. The electromotive force generated in the secondary coil is proportional to the induction, and we must deduct from it the loss in resistance in order to obtain the external electromotive force. Thus, if 1 per cent. be lost by resistance in the secondary, and 1 per cent. by resistance in the primary, the difference of available electromotive force between open circuit and full output will be 2 per cent. For good lighting this may be considered the permissible limit of variation, and on this basis I have calculated

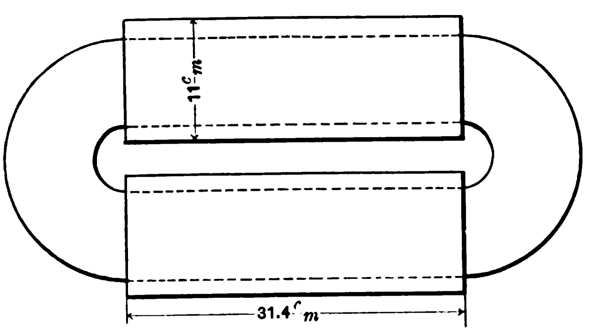

FIG. 8.

the output of the four transformers above described. Curve III in figure 6 gives the result for the circular and oblong Gramme ring. It will be seen that with a stout core the limit of output due to heating is reached sooner than that imposed by the condition of self-regulation, whilst for thin cores the reverse is the case. The best proportion of iron to copper is indicated by the intersection of curves III and II for the circular, and III and 2 for the oblong transformer. In the latter case the core would have to be 7.2 cm. in diameter, and the winding would have to be 1.4 cm. deep. The output is 5,900 watts. For the Zipernowski ring curve III gives the output as limited by self-regulation in the circular, and curve 3 in the oblong type. The diagram shows that the limit of output imposed by the condition of self-regulation is in all cases reached sooner than that due to heating. For the oblong transformer the maximum output is slightly below 5,000 watts, and the best proportion of iron to copper is given by the abscissæ of the highest point of curve 3. The external shell would have to be 2.4 cm. thick, and the sectional diameter of the coils 5.2 cm. From the above figures it appears that in the circular and in the oblong type the Gramme ring, dimensioned as shown in figures 2 and 8, gives more output than a Zipernowski ring of the same over all dimensions; the latter is therefore not superior to the Gramme ring, as commonly supposed, but somewhat inferior.

It might be, perhaps, objected that I have selected proportions different from those found in actual circular shell transformers, which have a much stouter ring of smaller mean diameter. More of the internal space is filled by the shell, and the central hole left is much smaller than shown in figure 3. The iron wire forming the shell is not put on in regular layers, but the turns cross each other in a more or less confused manner. There is no objection to such winding from an electrical point of view, as perfect insulation between the wires is of small importance. For the Gramme ring such winding would, on the other hand, be quite inadmissible; and it is on this account that I have selected a somewhat larger internal diameter of the rings, which gives room for regularly wound coils. But even if the rings are much stouter their proportion of output is not materially altered. If we imagine the ring of figure 3 contracted so as to reduce the central opening to 10 cm. and the extreme diameter to 32 cm., we obtain about the proportion of a Zipernowski transformer.

For convenience of calculation I have assumed a ring of these proportions to be changed into the oblong type, as shown in figure 8, but with this difference, that the external winding (coils or shell) on each side is only 15.7 cm. long instead of 31.4 cm.; the diameter being 11 cm., as before. Calculating the output in the same manner as before, I find that for the core transformer the maximum output as limited by heating is 3,230 watts, and is reached when the copper winding is 2 cm. deep, whilst the maximum output as limited by the condition of self-regulation (within 2 per cent.) is 3,020 watts, and corresponds to coils wound 1 cm. deep. The two curves cross each other as in figure 6, and the ordinate of the crossing point corresponds to a maximum possible output, as determined by the joint limit of heating and self-regulation, of 2,950 watts with coils wound 1.3 cm. deep. In the shell transformer the limit of output due to heating is 3,030 watts when the shell is 2 cm. thick, and the limit of output due to self-regulation is 1,650 watts when the shell is 2.2 cm. thick. These figures show that even in stout rings, having proportions more nearly comparable with those of the Zipernowski transformer as actually constructed, the core type is better than the shell type.

This result refers, however, only to transformers having a core or a shell of circular section; and the question is whether by an alteration in the form of the shell the shell transformer could be improved. Any departure from the circular form of the shell must increase the length of the magnetic circuit, and must so far be detrimental; but if we can at the same time reduce the length of the copper coils, this advantage may be more than balanced by the reduction in the resistance of the circuits. As a matter of fact, the magnetic resistance of the shell is so low that even a considerable increase in the length of the magnetic circuit does not materially affect the difference of phase between the primary and secondary current. The two are almost diametrically opposed whatever may be the magnetic resistance. We can, therefore, adopt any shape of shell which will allow the length of the copper coils to be reduced. This is actually done in most modern transformers. The shell is rectangular, with the short side of the rectangle parallel to the plane of the coils, and thus the mean diameter of the coils is reduced. In addition to this, the circular form of coils has been abandoned in several of the more modern transformers, so that the shell may fill more or less completely the interior of the coils.

In core transformers as now generally made the coils are not arranged all over the core, but are disposed of in two sets, one on each limb of a single core. Each set of coils contains a primary and secondary circuit wound upon each other, or one between the other, so as to obtain perfect symmetry. Were this not so, and were one limb wound with the primary and the other with the secondary, external poles would be formed at opposite points of the core, and the output would be reduced. In a similar manner the coils in shell transformers are wound upon or in between each other, but there is generally only one set of coils and a double core. The distinctive characteristics of the two types are therefore as follows:

Core transformers.—One core and two sets of coils.

Shell transformers.—Two cores and one set of coils.

The following are some of the principal modifications of each type:

Core transformers.—Gaulard & Gibbs, Lowrie-Hall.

Shell transformers.—Zipernowski, Ferranti, Mordey, Wright, Kennedy, Statter, Westinghouse, Snell & Kapp, Gaulard & Gibbs.

As most of these transformers are on the table, I need not describe them at length. The original Gaulard & Gibbs transformers had an open magnetic circuit, and cores which could be more or less inserted into the coils so as to regulate the E. M. F. of the secondary, a provision obviously necessary where the transformers are coupled in series. In the apparatus shown in 1883 at the exhibition in the Aquarium, there were four distinct induction coils; and in that employed for lighting on the Metropolitan Railway in 1884 there were 16 distinct induction coils, the circuits being formed by a compound cable consisting of a central primary wire and six secondary wires grouped round it. In 1885 was introduced a type of transformer with closed magnetic circuit. In the same year Messrs. Gaulard & Gibbs introduced small shell transformers in their Tivoli installation, each transformer feeding one 50 c. p. lamp. The two circuits are formed by a compound cable coiled into a solenoid, through which is passed a bundle of iron wires; the projecting ends are then bent over to close the magnetic circuit on the outside of the solenoid, and the whole is encased in a perforated metal cylinder with wooden ends. In their latest design of transformer the coils are circular in plan and rectangular in section, and are surrounded by groups of U-shaped soft iron stampings slipped over from both sides and held together by two circular cast-iron plates with a central bolt. The primary circuit is split up into two coils, with the secondary between them.

In the Lowrie-Hall transformer there are two sets of primary and secondary coils laid horizontally one above the other. The core is formed by thin broad sheets of soft iron insulated from each other by varnished calico, and the projecting ends of these

plates are alternately bent up and down respectively so as to complete the magnetic circuit, the whole being clamped together in a horizontal cast-iron frame. The Ferranti transformer is similar in the mechanical arrangement, but, belonging to the shell type, has only one set of coils of rectangular section. The core is formed of thin iron strips of moderate width insulated from each other, doubled over at the ends, and clamped in a cast-iron frame. Mr. Rankin Kennedy has devised various transformers of the shell type. For the general supply of alternating currents he proposes to use a main current transformer at the generating station, in which currents from low tension dynamos are to be converted into high tension currents to be sent into the mains. The shell of this transformer is built up of moderately wide but very thin strips, to form a rectangular frame of considerable depth, the strips being fastened by bolts at the corners. The core is composed of a series of strips of double width passing like a web through the middle of the opening of the rectangle, and thus subdividing it into two openings through which the winding passes. In another type, which Mr. Kennedy calls the "Piled Form of Subdivided Transformer," the iron portion consists of **H** stampings, in which the central web forms the core and the two down strokes of the **H** the shell, the coils being wound over the web. A number of these wound frames are piled upon each other, and side by side, the whole being clamped between cast-iron covers. Diagramatically, this construction can be represented by figure 1 if, instead of employing only two links, we use a number of them formed into a chain consisting alternately of copper and iron circuits. In another form of apparatus Mr. Kennedy uses a Siemens shuttle armature overwound with a shell of iron wire. Mr. Wright's transformer may be described as a Zipernowski ring with coils of rectangular section and a shell of rectangular iron frames instead of the original iron winding. Each frame is cut across a corner, so that it may be placed over the core; and as the edges are packed close on the inside, but radiate on the outside of the ring, the frames form gills for the dissipation of heat. In Mr. Mordey's transformer the shell consists of thin rectangular iron plates with a rectangular opening, the strip cut out being laid across the frame to form the core of the coils. The ratio in the length of the sides of the rectangle must evidently be as 4:6, and that of the strip cut as 2:4, in order to obtain a uniform section throughout the magnetic circuit. The apparatus is built up by alternately slipping a frame over and a strip through the coil. The core of the Westinghouse transformer consists of rectangular frames, each with a central web connected to the frame on one side only, so that it can be bent back to slip over the coils. The whole is mounted in a cast-iron weather-proof box for outdoor use. The shell in Mr. Statter's transformer consists of **E**-shaped stampings slipped over the coils alternately from either side. To obtain the same area of iron throughout, the width at the bottom of the stamping is twice that of the limbs. In the transformer designed by Mr. Snell and myself, the shell consists of **U** stampings forming a double trough into which the coils are laid. The covers of these troughs are formed from the metal removed from the interior of the stampings. The whole is held together in a cast-iron frame so arranged as to allow air to circulate through the core and round the coils.

To render transformers perfectly safe it is necessary to avoid leakage between the two coils. For this purpose Mr. Kent has devised a very simple apparatus, consisting of an insulated sheet of metal wrapped round the inner of the two coils, but not forming a closed circuit in itself. This sheet of metal, which thus separates the two coils completely, is connected to earth. Now, if the insulation of the primary coil should fail, the leak before reaching the secondary coil, must pass through the sheet of metal, and is thus conducted to earth, causing the primary cut-out to melt, and thus cutting the faulty transformer out of circuit. Another safety appliance has been devised by Captain Cardew. Its object is to disconnect the primary circuit from the mains if any part of the secondary circuit acquires a certain potential above that of the earth, which will take place if a leak occurs between the two circuits. The apparatus consists of a cast-iron box on the bottom of which is laid, into a shallow recess, a strip of platinum foil terminating at both ends in circular discs. About one-eighth of an inch clear above one of these discs is set a metal disc with screwed stem at the back passing through the glass cover of the box, and connected by a fine fuse wire with any point of the secondary circuit. The box itself is connected to earth. The fuse wire holds back a contact spring so arranged that on breaking of the wire it will fly down to its contact and short circuit the primary terminals of the transformer, after which its own primary fuse will melt and cut off the supply of current. If the potential between earth and the insulated disc in the box should rise above a certain limit (which can be regulated by screwing the disc up or down) the static attraction between the disc and aluminium foil lifts the latter into contact, allowing a leakage current to pass through the fuse wire of the contact spring, and thus releasing the latter. I am told by Captain Cardew that this apparatus has been tried at the Grosvenor Gallery installation, and been found to act in a perfectly reliable manner.

In the present paper I have only dealt with what may be called elementary principles in the construction of transformers. As, however, the application of transformers is a matter of far greater importance to our profession at large, I trust you will allow me to say a few words on this subject, not with the object of imparting information, but in the hope that a discussion of real practical value may be the result. Up to the present, distribution by transformers has been made either on the single-series or the single-parallel system; compound parallel, the three-wire system, or any other refinement of direct supply methods, have, to my knowledge, never been attempted with transformers. The series system must fail for want of self-regulation where the lamps are to be connected in parallel and controlled independently of each other; but for very extensive and sparsely lighted districts, with the lamps supplied by each transformer in series on the Bernstein system, a series arrangement of transformers will admit of perfect self-regulation, provided the primary current be kept constant, and will, moreover, be cheaper than the parallel system. For general purposes, and especially for the dense lighting required in towns, the only practical method at present in use is to connect the primary terminals of the transformers all in parallel, and the lamps also in parallel, across the secondary circuit of each transformer. In principle this arrangement is adopted in England, America, and on the continent; but the methods differ in these countries. Here the distribution is made by a high-tension network of mains, and the transformer of each subscriber is directly connected with the mains. In America a double network of overhead mains is employed, one for the high tension and the other for the low tension currents. These mains are supported generally on the same poles, to which are also fixed the transformers, and the subscriber's connection is made with the low tension mains wherever convenient. On the Continent a network of low tension underground mains is used for distribution in the same way as if the supply were on the direct system, and this network is fed by alternating currents at certain points where fairly large transformers are installed. The primaries are connected with the station either by overhead wires or by a special kind of cable containing two circuits insulated from each other and arranged concentrically. The cable is protected by a double lead covering and by an iron sheath formed of spirally wound tape. Of the three methods here described our own appears to be the worst, the American slightly better, and the Continental the best. To string high tension wires over and across our streets, allow high tension branch leads to pass into our houses, and give every subscriber a little transformer to himself, more or less within reach of the inmates, seems to me to be positively courting disaster. Such rough-and-ready methods may do as long as the light is not generally installed throughout a district; but once assume that every householder is using it (and it is that we are hoping for), the thousands of branch wires and transformers in the houses must constitute a very serious element of danger. In the American plan the high tension wires are not brought into the houses, and in so far there is little danger to the inmates; but of course in the streets there is the same danger as here from overhead wires.

Now the Continental plan may almost be called absolutely safe. With an arrangement like Mr. Kent's dividing sheet to prevent leakage, or Captain Cardew's ingenious apparatus for detecting it and cutting off the supply, the secondary circuit can never acquire a potential sufficiently high to endanger life or property. This network can be composed of comparatively light cables, because we can feed it at frequent intervals, and thus insure constancy of pressure at all places and at all hours. The transformers would be fairly large—say from 500 to 1,000 lights each—and could be installed in rooms to which no person but the authorized attendant has access; and by placing the primary feeding mains also underground accidents would be rendered almost impossible. The method of using an underground secondary distributing network has also the advantage that, should at any future time storage batteries become sufficiently improved to render distribution by continuous currents possible, the whole of the cables would be available for this purpose without any change.

THE COMPARATIVE VALUE OF THE CONTINUOUS AND THE ALTERNATING CURRENT SYSTEMS FOR THE COMMERCIAL DISTRIBUTION OF ELECTRICITY.[1]

BY H. WARD LEONARD.

THERE exists to-day a great deal of uncertainty in the minds of many persons interested in the distribution of electric energy as to the comparative value of the continuous current three-wire system and the alternating current converter system; and as the published statements relative to these two systems have apparently greatly exaggerated certain advantages and disadvantages of the one system and the other, I will endeavor to institute what I consider as fair a comparison as possible between the two systems, using the best data at my command, and giving due weight

1. Abstract of a paper read before the Chicago Electric Club.

to the several factors necessary in a general system for the distribution of electric energy on a commercial scale.

In considering the comparative value of these two systems, let us compare them with each other upon the following points, which I consider the vital ones in a general supply system of electric energy.

First. First cost.

Secondly. Economy, efficiency and depreciation.

Thirdly. Reliability.

Fourthly. Variety and value of the possible sources of revenue.

Fifthly. Safety to life.

Sixthly. Effects upon existing property.

First Cost and Economy.—This is a feature which is subject to variations which are not similar in the two systems, and it may be well to give some general explanations of the cause. In a three-wire system the principal items of cost are the generators, main conductors and inside wiring. In the alternating system the main items of cost are generators, primary circuit, converters and secondary circuit.

The cost of the generators is, as far as I am able to judge by inspection and comparison of prices, about the same. At any rate, any possible difference in this respect must necessarily be but slight in its influence on the total cost of which it becomes a very small factor. We, therefore, come to a comparison between the cost of the feeders, mains and inside wiring of the three-wire, and the cost of the mains, converters and inside wiring of the alternating system.

The cost of the conductors transmitting a given amount of energy at a given loss for a given distance varies, generally speaking, inversely as the square of the initial electromotive force employed. For instance, if the E. M. F. of one system be 1,000 volts, and that of another be 110 volts, the cost of conductors for the latter under similar conditions would be to the cost of the former as 1,000,000 ($1,000^2$); 12,100 (110^2); *i. e.*, as 82: 1.

In the three-wire system double the E. M. F. of the lamps is used, and the practical effect is the same as if the lamps were operated in series as far as the two outside conductors are concerned.

We saw that the cost of a conductor for a 110 volt two-wire system and a 1,000 volt converter system was as 82 is to 1. It is now evident that by using the three-wire system this ratio becomes as 27.5 is to 1.

The three-wire system is not, of course, limited to the electromotive force quoted. The Edison company operate dynamos of 1,200 volts in a three-wire system for their municipal system.

The standard three-wire system of to-day is limited by the difficulty in manufacturing lamps of much higher voltage than 110. When the time comes, and it seems near at hand, that lamps can be had of double the voltage of those, the cost of conductors of the three-wire system will be one-fourth of what it is to-day; or, in other words, existing conductors will be able to supply four times as many lamps as at present, and at the same loss; also, an increase in the economy of the incandescent lamps would reduce the cost of conductors proportionately, and we can, of course, expect to see very great improvements in this direction.

It is evident, therefore, that the cost of conductors in the three-wire system will be reduced by inevitable improvements in the lamp itself to but a small fraction of its present cost.

Now let us look at the alternating system under similar conditions. Outside of the generator the converter is the principal item of cost, the cost of conductors being slight in comparison, as we will see later. An increase in the voltage of the lamps would be of no benefit whatever, and an increase in the economy of the lamps would result in a proportional reduction in the cost per lamp. Let us suppose that the voltage of existing lamps be doubled, and the economy increased 25 per cent., both of which results are likely to be seen in a very few years, if not sooner. The cost of conductors for the three-wire system would be reduced 80 per cent., and the cost of converters would be reduced 20 per cent., or, in other words, existing three-wire conductors would be able to supply five times as many lamps as at present, an increase in capacity of 400 per cent., and existing converters would be able to supply 25 per cent. more than at present.

So much for the probable reduction in first cost consequent upon improvements in the economy of the lamp itself, the only place in any incandescent system where much increase in economy can be expected, as existing devices are all claimed to have, and most of them do show an individual efficiency of 90 per cent. and upwards.

Let us now examine the comparative cost, as these systems exist to-day. In order to do this, it becomes necessary to determine the cost of conductors under the varying conditions met with in practice; and this can be conveniently done by applying the following formula deduced by the writer, the accuracy of which has been tested by practical use for about two years:

Let *T. C. P.* be total candle-power.

Let *D* be the mean distance current travels (one way).

Let *L* equal price per pound of copper (in cents).

Let *V* be volts lost in conductors (both ways).

Let *E* be E. M. F. of lamps.

Let *C. H. P.* be candles per electrical horse-power.

$$\text{Then } \$ \quad \frac{T.\,C.\,P. \times D^2 \times L}{V \times E \times C.\,H\,P. \times 1{,}000}$$

For the three-wire system, one third of this value is to be taken.

Before proceeding to apply the formula, let us clearly understand that with a continuous current the loss in conductors is

exactly proportional to the amount of energy they transmit; *i. e.* any variation in the load causes a proportional variation in the loss in conductors.

With the alternating current this is not the case, the decrease in the energy transmitted resulting in but a slight decrease in the current. Thus, with a continuous current the loss in conductors under conditions of one-quarter load is one-quarter what it is at full load, but with the alternating current the loss in conductors at one-quarter load is probably 75 per cent. of what it is at full load. However, as this conclusion is based mainly on theoretical grounds, I will, in comparison, grant that the alternating current will be as efficient in this respect as the continuous current.

Careful examinations of the load diagrams of some 50 Edison central stations, show that throughout the run the average load is from 33 to 40 per cent. of the maximum load; *i. e.*, if the loss in conductors is 10 per cent. when the full load is on, the average loss throughout the whole time the plant is supplying light is but 4 per cent.

Table I shows the maximum loss expressed in volts, the corresponding maximum per cent. of loss, the corresponding average per cent. of loss, and consequently the average efficiency of the system of conductors:

TABLE I.

System.	Three-wire system.			1,000 volt alternating current system.		
Maximum loss in volts	12.5	20	30	25	50	100
Maximum loss in per cent	10	15	20	2.5	5	10
Average loss in per cent	4	6	8	1	2	4
Average efficiency	96	94	92	99	98	96

These two tables show the individual efficiency of the different portions of the two systems, and the total efficiency from the driving belt up to and including the portions named. I have granted in all cases for the converter system an efficiency of 98 per cent. for the primary, and 99 per cent. for the secondary conductors. With a commercial efficiency of 90 per cent. for the generator and 95 per cent. for the converter, which is sometimes claimed for them by some, the total efficiency is 82.9 per cent. With a commercial efficiency of 85 per cent. for the generator and 90 per cent. for the converter, which is believed by others to be liberal, the total efficiency is 74.2 per cent. In the three-wire system we have assumed an efficiency of the generator of 92 per cent., which result is obtained by every maker of a first-class dynamo of this type, and an efficiency of 99 per cent. for both the mains and the inside wiring, both of which portions of the system are in practice calculated for a maximum loss of 2 per cent.

The maximum loss in the feeders in table number 2 is made 10, 15 and 20 per cent., with a corresponding average loss of 4, 6 and 8 per cent., and an efficiency of 96, 94 and 92 per cent.

TABLE II.

Alternating current converter system.

—	Indv.	Total.	Indv.	Total.	Indv.	Total.
Efficiency of generator	90	90	88	88	85	85
Efficiency of feeder	98	88.2	98	87.2	98	83.3
Efficiency of converter	95	83.8	92	79.3	90	75
Efficiency of services and inside wiring	99	82.9	99	79.5	99	74.2

Three-wire system.

—	Indv.	Total.	Indv.	Total.	Indv.	Total
Efficiency of generator	92	92	92	92	92	92
Efficiency of feeder	96	88.2	94	86.5	92	84.6
Efficiency of mains	99	87.3	99	85.6	99	83.7
Efficiency of services and inside wiring	99	86.5	99	84.7	99	82.9

Assuming the highest efficiency claimed for the alternating current generator, and assuming the generator is as efficient as a continuous current generator under conditions of partial load—which is not likely—and assuming that the converter has the same efficiency under partial load as under full load—which we know cannot be—we still are met with the fact that the three-wire system with a maximum loss of 20 per cent. in the feeders has as high an efficiency as the converter system, allowing it every possible claim, and that the three-wire system as usually installed, with a maximum of 10 per cent. loss in feeders, has a superior efficiency of from 4 to 12 per cent. over the alternating current converter system.

To return now to the question of first cost. Assuming the cost of copper at 16 cents per pound, I have figured the cost of copper conductors for feeders for 16 candle power, 50 watt lamps for distances of 1,000, 2,000, 3,000, 4,000, 5,000 and 6,000 feet, with an average loss in conductors of 4, 6 and 8 per cent. for the three-wire system, and 2 per cent. for the alternating system with 1,000 volts initial E. M. F.; cost is expressed in dollars and decimal fractions thereof.

TABLE III.

Cost of copper for three-wire feeder per 16 c. p. lamp (50 watts, 110 volts). Copper at 16 cents per lb.

Distances	1,000	2,000	3,000	4,000	5,000	6,000
12.5 volts maximum loss equals 5 volts average loss, which is 4 per cent	.266	1.064	2.394	4.256	6.65	9.576
20 volts maximum loss equals 8 volts average, which is 6 per cent	.1615	.646	1.453	2.584	4.037	5.812
30 volts maximum loss equals 12 volts average, which is 8 per cent	.1077	.430	.969	1.723	2.69	3.87

Cost of primary and secondary circuits and converters for 1,000 volt alternating current converter system, per 16 c. p. lamp, at varying distances.

Distances	1,000	2,000	3,000	4,000	5,000	6,000
Primary	.0213	.065	.191	.340	.530	.764
Converter	3.000	3.000	3.000	3.000	3.000	3.000
Secondary	.240	.240	.240	.240	.240	.240
Total	3.2613	3.325	3.431	3.580	3.770	4.004

I have also calculated the cost of copper in the mains for one 16 c. p. lamp on the basis of a distance of 800 feet between feeder terminals in the three-wire system and a maximum loss of 2 per cent. and find it to be 13 cents. Also the cost of services and inside wiring in the three-wire system on basis of an average distance to lamps of 100 feet, and 2 per cent. loss, and since the full benefit of the three-wire distribution cannot be attained in the inside wiring, have assumed the saving of one-third over the two-wire system instead of the two-thirds saving effected in cases where the full benefit can be attained. On this basis the cost of copper for services and inside wiring is six and one-half cents per lamp.

In the alternating current converter system I have assumed the cost of converters recently quoted by Mr. Stanley, the electrician of the Westinghouse company, in a paper before the Boston Society of Arts. This figure is three dollars per lamp. I have calculated the cost of copper per 16 c. p. 50 volt and 50 watt lamp with an average distance to the lamp of but 75 feet, and with 2 per cent. loss, and found the cost of copper to be 24 cents per lamp. With an average distance of 100 feet, as was assumed in the case of the three-wire system, the cost of conductors for the inside wiring would be 43 cents. In making the comparisons, however, we will give them the advantage due to the 75 feet distribution; that is, 24 cents per lamp.

I have plotted these results, expressing cost as ordinates, and distances as abscissæ. The curves resulting are here shown. See diagram.

In the diagram curve No. 1 shows cost of primary converter and secondary for alternating system (converters at $3 per lamp).

No. 2 shows cost of primary and converter for alternating system.

No. 3 shows cost of primary for alternating system.

No. 4 shows cost of feeders for average loss of 4 per cent.

No. 5 shows cost of feeders for average loss of 6 per cent.

No. 6 shows cost of feeders for average loss of 8 per cent.

No. 7 shows cost of feeders and mains for average loss of 9 per cent.

No. 8 shows cost of feeders and mains in the three-wire system for average loss of 6 per cent.

No. 9 shows cost of feeders and mains in the three-wire system for average loss of 8 per cent.

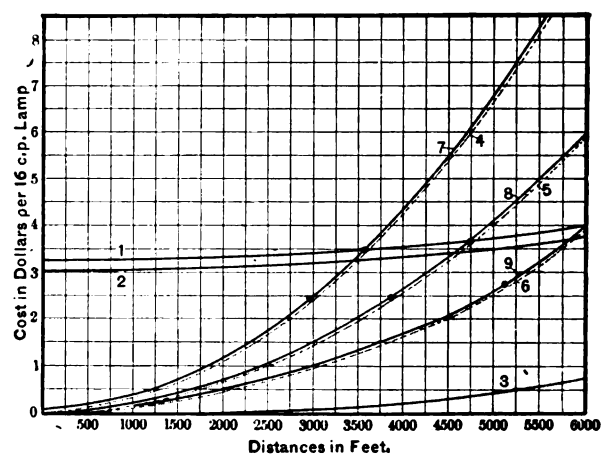
In the three-wire system curves for total cost are the lines in black just above the dotted lines.

It will be seen that if the three-wire system be operated at an average efficiency of 92 per cent. in the feeder, which corresponds to the highest efficiency claimed for the alternating current converter system, the total cost per lamp would be equal when the average length of feeder was 6,000 feet. An average length of feeder of 6,000 feet corresponds to a circular area 18,000 feet in diameter—that is, about 3½ miles in diameter. In practice, it is preferable to operate at higher efficiency, making a large investment in copper, which has the strong recommendation of having the least depreciation, and requiring the least attention of anything used in connection with the transmission of energy.

The middle curves represent an average efficiency of 94 per cent. in the feeder: that is, an average loss of 6 per cent. in the feeder. You will notice that even with this superior efficiency the three-wire system is cheaper per lamp than the alternating current converter system at an average length of feeder of 4,750 feet, corresponding to a circular area of 12,000 feet in diameter, and that for shorter distances the cost rapidly diminishes—the cost of conductors for three-wire system at this efficiency with an average length of feeder of 3,000 feet corresponding to a circular area 9,000 feet in diameter, being less than one-half the cost of conductors and converters for the alternating system.

Even with the very high efficiency of 96 per cent. in the feeder, or an average loss of but 4 per cent., the conductors of the three-wire system are cheaper than the conductors and converters of the alternating current converter system for an average length of feeder of 3,600 feet or less, and this corresponds to a circular area 11,000 feet in diameter.

Suppose that both the generator and converter are so much cheaper than we have assumed as above that it makes a total



reduction of $1 per lamp. We then find that under conditions of equal efficiency, 82.9 per cent., the three-wire is cheaper where the average distance to lamps is one mile or less. With the usual efficiency for the three-wire system, 84.7 per cent., it is the cheaper for an average distance to lamps of 4,000 feet, or less, and with the highest efficiency, that is 86.5 per cent., with average loss of 4 per cent. in the feeders, the three-wire system would be the cheaper when the average distance to lamps is 3,000 feet or less.

Suppose, on the other hand, that the incandescent lamp be doubled in voltage, and increased 25 per cent. in economy; at the same time that the cost of converter was reduced to two-thirds its present cost, and we find that with the highest efficiency, 96 per cent. in the feeders, the three-wire system would be the cheaper for cases where average distance to lamps is 8,000 feet or less, which corresponds to a circular district about five miles across.

Before leaving the question of economy of operation, let us look at the question of depreciation. In any dynamo the depreciation naturally becomes greater when it is operated at high E. M. F., even where the type is the same, and in the high E. M. F. alternating current generator there exists the greatest tendency toward troubles due to the breaking down of the insulation of the wire on the armature. The secondary circuit of the alternating current system and the inside wiring of the three-wire system would have a similar depreciation, but there is a great difference between the depreciation of copper conductors carrying low E. M. F. continuous currents and the depreciation of highly insulated conductors carrying a high E. M. F. alternating current, together with the depreciation on an expensive piece of apparatus like the converter, the large proportion of the cost of which is represented by labor. Try to compare the value of copper 20 years hence which costs $1,000 to-day with $1,000 of converters, and small highly insulated wire such as is used in the primary circuit of the alternating system, and I think it will be evident that the depreciation of the alternating system is going to be many times that of the three-wire system.

THE DEVELOPMENT OF THE MERCURIAL AIR PUMP.[1]

BY PROFESSOR SILVANUS P. THOMPSON, D. SC., B. A.

(Continued from page 58.)

In 1881, Mr. Rankin Kennedy[2] prepared a pump for exhausting lamps, going back in principle to that of Baader. Mercury is passed down a supply tube, S (figure 16), and rises with the pump-head, expelling the air through a valve, V. Then a three-way eject tap, E, at the bottom is turned, cutting off communication with S, and allowing all the mercury in the pump-head to run out into a basin below. The lamp, or other vessel, R, to be exhausted, is joined in through an aperture at the top of the pump-head by means of a tube passing in through an India-rubber cork, *c*, and sealed above by a mercury joint. This tube is also supplied with an automatic valve, *v*, at its lower end, to allow it and the exhausted lamp to be removed from the pump, in order to seal it off. A similar device had also been described by Akester. Akester's pump[3] closely resembled that of Lane-Fox; but in it the raising and lowering of the supply vessel was obviated by using, at the bottom of the pump-shaft, a three-way tap, enabling the barometric column to be placed alternately in communication with a supply cistern placed at a high level, and with a return pipe through which the descending mercury flowed away at a lower level, to be again pumped up to the high level by a me-

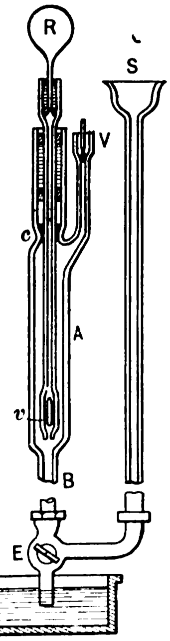


Fig. 16.

Kennedy's Pump.

chanical pump. Another way of raising and lowering the mercury in the pump, which also dispensed with flexible tubing, was suggested by Rock.[4] (A similar device was suggested by Mile in 1830.) The pump-head and barometric column are formed by a single straight cylindrical tube, about 100 centimeters long, 10 centimeters in internal diameter of glass, and one centimeter in thickness. It is open at the bottom, but closed in and furnished with the usual three-way tap at the top. Outside it is a second, slightly longer, tube, having an internal diameter of 12.6 centimeters. This—the supply vessel—is closed at the bottom, and can be raised or lowered mechanically. If the outer one, filled with quicksilver, is raised, the liquid forces its way up the inner tube, driving the air before it, through the three-way tap. When it is lowered, the mercury remains inside, to a height which will never exceed 76 centimeters above the level of the mercury in the outer tube, the space above being left vacuous. The inventor claims that this construction is less liable to give trouble than the usual form. Cruto[5] has used a somewhat similar device, but with sulphuric acid instead of mercury in the pump. To obviate having to work with a pump shaft 20 feet long, he adopted the device of an auxiliary exhaust pump. Narr[6] has described a simple pump on Jolly's plan, but having steel taps, the pump head of glass having united above and below to the working parts by carefully ground and lightly greased steel unions, clamped together by screws. By reason of its strength, this construction seems to be preferable in cases where very high vacua are not required.

Double-action pumps have been suggested by various persons. Kemp's pump (figure 8) was of this class, so is one by Serravalle,[7]

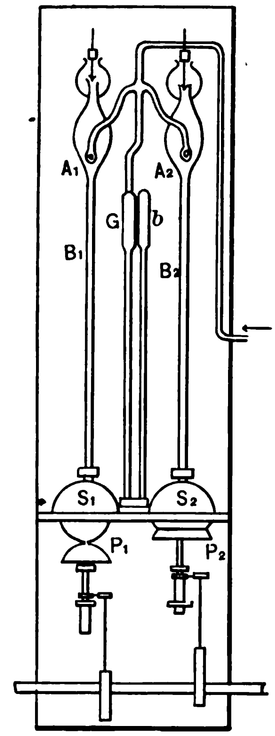

Fig. 17.

Gardiner's Double Pump.

in which there are two supply vessels, so arranged that while one rises the other descends; two separate pump-heads, with two three-way taps automatically opened and shut; and two exhaust tubes uniting into one. Another double pump, by Gardiner,[8] de-

pistons, P_1, and P_2, which press in the flexible hemispherical bottoms of the two supply vessels. The valves of this pump are all automatic, as in Kemp's pump. It is provided with a barometric gauge, G, and a comparison barometer, b. This pump was in use for some time at the Gülcher company's works at Battersea.

SUB-CLASS Ia.—SHORTENED UPWARD-DRIVING PUMPS.

The length of the pump-shaft in the preceding cases being necessarily equal to that of the barometric column, renders all these forms of apparatus more or less unwieldy. Although a column of mercury 76 centimeters high is a necessity for working between vacuum within and atmospheric pressure without, no such length is required when working between vacuum and a reduced pressure. In fact, the length of the pump may be shortened by reducing the pressure of the air above the surface of the mercury in the supply vessel, in all pumps of class I. and class II. The first suggestion for shortening the pump came from the Rev. Professor Robinson,[1] in 1864, and was almost immediately followed by one from Professor Poggendorff.[2] In these apparatus a common air-pump worked by hand was used to produce a partial vacuum. The pump-shaft was quite short, and ended in an auxiliary chamber, closed at the top, but having a tap communica-

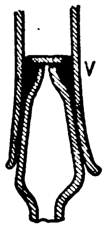

Fig. 19.

Detail of Valve.

ting either with the auxiliary pump or with the outer air. The three-way tap above the pump-head also opened into a tube which could be made to communicate either with the auxiliary pump or with the outer air. To fill the pump-head with mercury, air was admitted to the auxiliary chamber, whilst at the same time the auxiliary pump was applied at the top to suck the mercury into the pump-head. The three-way tap being then turned to put the pump-head into the vessel to be exhausted, the auxiliary pump was used to reduce the pressure in the auxiliary chamber, causing the mercury in the pump-head to fall, the height of the column representing always the difference between the pressure in the pump-head and that in the chamber.

Several later experimenters have adopted this device of applying an auxiliary pump to shorten the vacuum pump; and as we shall see, the device is applicable to each of the three main classes of pumps. Dr. F. Neesen,[3] whose more recent pump is described later, adopted this device in 1878. At that date he was employing a shortened Geissler pump, to which, independently of Mitscherlich, he had applied an automatic exit-valve above the pump-head. He had also introduced another notable improve

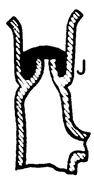

Fig. 20.

Schuller's Mercury Valve.

ment, namely, a side-tube, connecting the exhaust-tube from a point a little beyond where it branched off from the pump-shaft to a point above the pump-head below the automatic valve. Such a side-tube, marked N, in the figures 18 and 33, prevents the fracture of the top of the pump-head by air bubbles suddenly rising through the mercury in the barometric column.

Schuller,[4] in 1881, described another shortened pump, with numerous carefully considered details, and a curious automatic method of operating, which, however, need not here be described. Figure 18 shows Schuller's pump. V and U are automatic valves consisting of small pieces of flat glass, preferably triangular, which close the mouths of tubes that have been also carefully ground flat. In the valve V, shown in detail in figure 19, the weight of the small glass plate is partly sustained by the ring of mercury surrounding the tube end above which it lies.

Another feature of Schuller's pump is the valve J, situated in the tube between the pump-head and the upper valve V. This valve J, shown larger in figure 20, is composed wholly of mercury, which, during the descent of the body of liquid down the tube, forms, by virtue of its great surface-tension, a cap over the orifice three millimeters in diameter, which is here interposed. As in Geissler's later pumps, there is an auxiliary chamber, M, between V and J, in which a partial vacuum is formed, so that the residual air expelled from the pump-head is driven into an already exhausted space. The little vault of mercury over the aperture in J, is able to withstand the difference of pressure between the partial vacuum above and the nearly perfect vacuum below it. At the commencement, a partial vacuum is made in the pump-head, through the upper valve, by an auxiliary mechanical pump. A three-way tap, Y, suffices to put the space in the bottle, L, alternately into communication with the atmospheric air, and with a tube leading to an auxiliary mechanical air pump.

Another pump of this class, by Dittmar,[5] has simply two plain glass taps, one above, the other in the exhaust tube at the side of the pump-head. It obviously could not give a good vacuum.

The most recent pump in this category appears to be that of M. A. Joannis.[6] The ordinary three-way tap at the top of the pump-head communicates with the open air; below, at the lower end of the pump shaft, is a closed vessel, communicating by another three-way tap with a water aspirator, and with a source of pressure by means of which the mercury is alternately raised and lowered.

CLASS II.—DOWNWARD-DRIVING PUMPS.

The idea of expelling the residual air down a barometric column originated with Dr. Hermann Sprengel,[7] who in the year

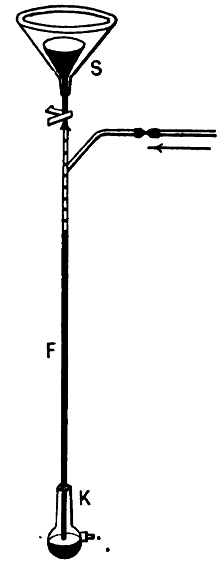

Fig. 21.

Sprengel's Pump. (Simple Form.)

1865 brought out the pump which is associated with his name. He had in the preceding years been studying the uses in the laboratory of the water trombe or aspirator, a much older instrument, used for some hundreds of years for delivering air under pressure. The theory of this ancient apparatus had already received the attention of Magnus,[8] and of Buff,[9] and Sprengel[10] had himself devoted some attention to this method of furnishing air for the blow-pipe. It appears to have been an original idea with him to substitute falling mercury in the place of falling water, in order to extract gases by means of the vacuum produced above the column.

The form of the original Sprengel pump is shown in figures 21 and 22. The supply vessel S, was, in this case, a funnel fixed at the top of the apparatus, from which the mercury was delivered at a steady rate through a narrow India-rubber tube, nipped by an adjustable pinch-cock. After passing this point it fell in drops down a glass tube, F, of narrow bore, but having strong external walls, and known as the fall-tube. As it fell down this tube in

drops, it swept out the air of the tube and the air which entered from the side, each drop acting as a piston to propel the air below it. To secure this action, it is essential that the fall-tube should not be too wide. For rapid, partial exhaustions, an internal bore of two to three millimeters appears to be about the best size; for slower exhaustions, carried to the highest degree of rarefaction, a bore of 1 4 to 1.8 millimeters appears to be preferable. During the first stages of the process of exhaustion, whilst yet there is a considerable amount of air in the fall-tube, the successive drops of mercury move separately down the tube, almost silently, being separated from one another by the intervening cushions of air, which, as they descend the tube, become more and more compressed. As a higher degree of rarefaction is attained there is no longer a sufficient cushion of air, the drops fall smartly through the vacuous space with a loud metallic clinking sound as they strike upon the top of the barometric column, which occupies the lower 30 inches or so of the fall-tube. At the bottom of the fall-tube the air and mercury enter a suitable vessel, K, from which, if desired, the air that has been carried down the fall-tube may be collected. The mercury which flows into K must be periodically collected and poured again into the supply funnel at the top. In the second form, figure 22, a downward bend is inserted between the supply funnel and the point where the mercury begins to break away into drops. This bend leads to a small chamber, virtually the pump-head, from the end of which the mercury falls in drops. The flow is regulated by a pinch-cock, which can be screwed up to nip, more or less tightly, a piece of flexible India-rubber tubing inserted in the supply tube. In this figure there is also shown a small mechanical air pump for rapidly producing

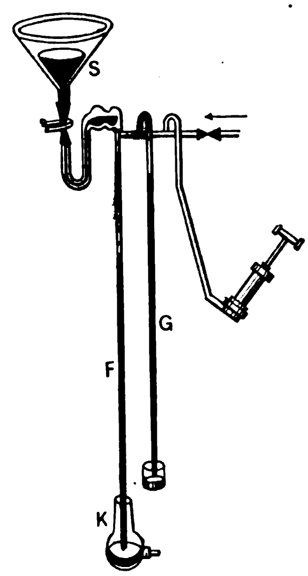

Fig. 22.

Sprengel's Pump. (Second Form.)

the first partial exhaustion, and barometric gauge, *b*, to show the degree of rarefaction attained.

The introduction of the Sprengel form of pump at once attracted a revived attention to the advantages of mercurial pumps for exhausting, and it was soon in the hands of many experimenters. Graham[1] applied it to extract minute quantities of gases in his researches on gaseous diffusion; Bunsen[2] adapted it for the purpose of hastening filtration, employing a form somewhat modified to admit of the use of drops of water instead of drops of mercury. Improvements began to be introduced in the details of construction, as experience revealed the imperfections. It was found that air was liable to be carried down into the pump through the supply vessel at such times as more mercury was poured in above; it was necessary to trap off such air bubbles to prevent them from vitiating the vacuum already attained. It was found necessary to introduce vessels containing drying materials, such as concentrated sulphuric acid, or glacial phosphoric acid. The fall tubes were found to have an awkward habit of cracking and breaking off just at a point 30 inches above the lower end, in consequence of the hammering action of the falling drops during the later stages of exhaustion. Better and more reliable gauges were required to verify the degree of rarefaction. Lastly, some remedy was wanted for the difficulty experienced in forcing down through the 30 inches of barometric column the last small traces of residual air in the fall tube. The falling drops hammered these residual bubbles into the mercurial column below them; the air bubbles, on their part, always tended to rise again into the upper part of the tube; often they would stick to the wall of the glass tube, refusing to move, though the mercury continued to flow past them. The remedy of turning on a more sudden flow of mercury to sweep them out was not always successful. Indeed, when it is remembered that these last residua must be recompressed to atmospheric pressure, in order to expel them at the bottom of the tube, it would seem strange if such a method of expelling the residual air should prove effectual. Some of the desired improvements were originated by Dr. Sprengel himself, others by instrument makers, who constructed Sprengel pumps for their customers.

An improved joint, made by grinding the conical end of a glass tube in a conical socket at the end of another tube, and placing mercury in the cup surrounding the junction, was described by Dr. Sprengel.

By the year 1874[3] two modifications had come into extensive use; the mercury, instead of running direct into the pump from the supply vessel was carried down a vertical tube, surrounded by a wider external one, so that any air bubbles accidentally carried down escaped up the wider tube instead of entering the pump; also after passing this trap, the mercury was forced up again in moderately wide tube, ascending to a slightly lower level than the supply vessel, and again descending. The upper bend of this tube communicated at its highest point with a small stoppered chamber, partially exhausted of air by filling it with mercury, which was then allowed to run out. As the mercury passed over this bend, it consequently fell through a partially exhausted space, and was still more thoroughly freed from air before ascending to the head of the actual pump. These improvements are embodied along with others in the form constructed by Alvergniat,[4] of Paris, who worked for and with the advice of M. H. Sainte-Clare Deville.

In most of the modern Sprengel pumps the mercury is introduced into the pump head by a jet tube with a narrow orifice, whence it spurts in a fine stream, and falls into the widened tube of the fall tube; in some other forms it merely breaks away in drops over a bend in a wider tube. This form is simpler to construct.

A very important addition was the improved gauge introduced by McLeod,[5] in which was applied the principle of compressing a known volume of the rarefied air or gas into a smaller known volume (the ratio of the two volumes being accurately known) and then measuring its pressure, and so calculating backwards. This method, suggested long before by Arago, and employed by Régnault[6] for the purpose of testing the perfection of the vacuum of a barometer, may be regarded as a refinement upon the method of the "pear gauge" invented by Smeaton. In Smeaton's invention the residual air left in the pear-shaped glass vessel, placed with its lower end in mercury, under the receiver of an air pump was, on the restoration of the external pressure, driven out of the body of the pear into its narrow upper end, where its volume could readily be measured. In McLeod's original gauge a globe of about 48 cubic centimeters was employed, opening at the top into a narrow volume tube seated at the top, and suitably graduated. This apparatus communicated below with the pump, and stood at the top of a barometric column which was provided at its foot with a flexible rubber tube and a supply vessel, by raising which (by an action like that of Geissler's pump) the mercury could flow up into the gauge, and force the residual air in the bulb into the volume tube at the top. A neighboring pressure tube rendered the increment of pressure (due to compression) evident at a glance, and all that remained to be done was to multiply this increment by the ratio between the volume now occupied by the residual air and volume it originally occupied. McLeod showed how to carry the calculation to a second approximation.

About the same time Crookes[7] introduced several improvements in detail:—A method of lowering the supply vessel to refill it with the mercury that had run through the pump; the use of taps made wholly of platinum to ensure tightness; the use of a spark gauge to test the perfection of the vacuum by observing the nature of an electric spark in it; the use of an air trap in the tube leading up to the pump head; the method of connecting the pump with the object to be exhausted, by means of a thin, flexible, spiral glass tube; the method of cleansing the fall tube by letting in a little strong sulphuric acid through a stoppered valve in the head of the pump. In carrying out these experiments, Crookes was assisted by Mr. Gimingham, whose further

contributions to the development of the pump will presently be noticed. It was with this improved pattern of Sprengel that Crookes was able to carry out that remarkable series of researches upon the repulsion accompanying radiation, which culminated, in 1875, in the invention of the radiometer, and later led to the discovery of the phenomena of "radiant matter."

Professor R. A. Mees[1] described another modification, the fall tube being constructed with a series of bends constituting fluid

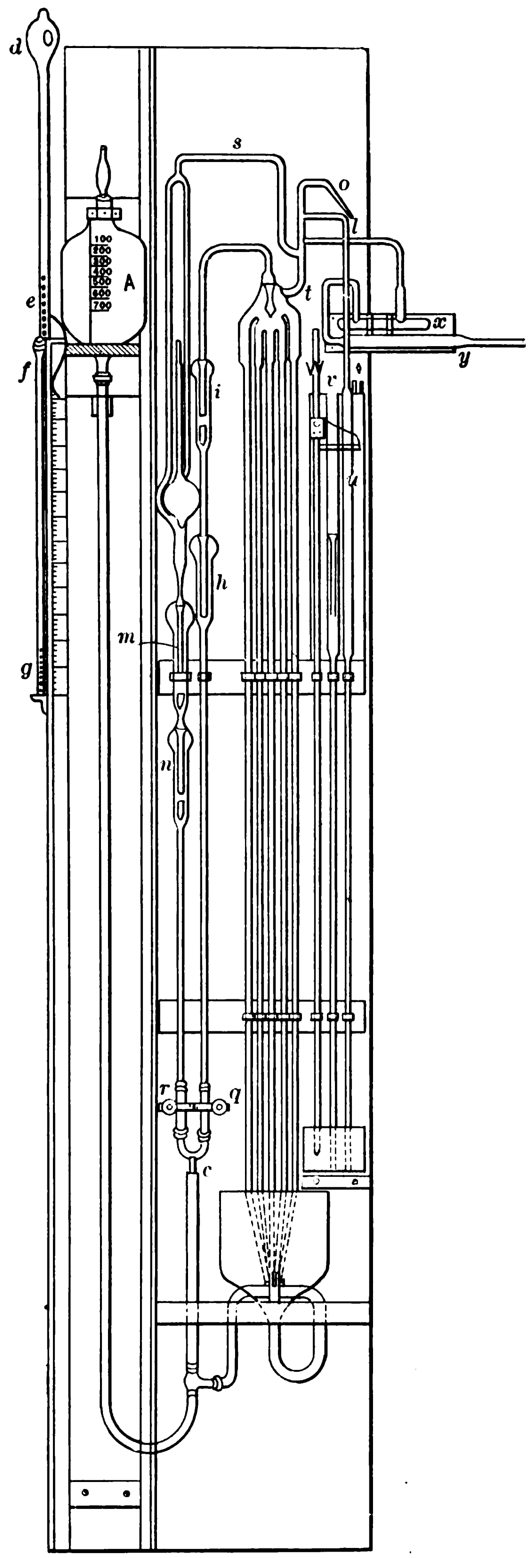

Fig. 23.

Gimingham's Pump.

valves or traps, in which the minute portions of air carried down the fall tube might accumulate in order to be swept out the more effectually when aggregated in larger bubbles. This pump also had a peculiar automatic stop cock.

From 1875 to 1884 a series of modifications were introduced by Mr. Gimingham.[2] Firstly, the process of exhaustion was accelerated by the employment of multiple fall tubes, receiving their streams from a distributing jet within the pump head. Three fall tubes were employed, then five, later seven; but five appears to be a preferable number. In figure 23, which embodies Gimingham's various improvements with the earlier ones of Crookes, there are five fall tubes shown. Careful experiments to determine the best size of bore for the fall tubes gave the following results when exhausting a vessel of 136 cubic centimeters capacity :—

Diameter of bore in millimeters.	Rate of flow in cubic centimeters per minute.	Total quantity of mercury in cubic centimeters requisite to reduce pressure to one millimeter of mercury.	Total time required. in minutes.
2.4	83.3	2,500	30
2.4	20	1,600	80
1.8	20	700	35
1.8	50	1,200	24
1.4	10	1,800	180
1.4	25	2,700	120
1.1	20	4,000	200

The enormous time required in the last case was due to incessant choking up of the upper part of the fall tube, owing to friction in the narrow bore. The conclusion derived from comparison of results with varying bores is that at high degrees of exhaustion the last portions of air or gas are carried out by entanglement with the mercury, and not by the mercury acting in definite "pistons" to sweep out the gas. With respect to the length of the fall tubes, it was found that those 39 inches (1 meter) long, giving a fall of 9 inches (or 22.5 centimeters), exhausted more rapidly than tubes only 33 inches (85 centimeters) long. Tubes longer than 39 inches were found liable to fracture, in consequence of the severe concussions of the mercury as it fell upon the top of the barometric column. Gimingham also described an improvement in the McLeod gauge, making its indications at once more sensitive and more reliable. Several minor improvements are also mentioned; an improved vacuum tap, an improved form of air trap, a radiometer gauge, and a bulb containing crumpled gold leaf, to absorb mercury vapor.

The lettering in figure 23, which is taken from Gimingham's paper in the "Journal of the Society of Chemical Industry," is as follows: The supply vessel, A, communicates by a long tube with a forked tube, C, leading to two regulating pinch cocks, *r* and *q*. The left-hand tube leads up through two air taps, *n* and *m*, to the McLeod gauge; the right-hand tube, through two air taps, *n* and *i*, to the pump head, where the mercury is thrown in jets into the tops of the five fall tubes. The tube, *t*, is the exhaust tube, which has three branches, one, *s*, leading to the McLeod gauge, one, *l*, leading to the barometric gauge, *u*, and one leading through the drying tube, *x*, and the absorbing tube, *y*, to vessel, lamp, or bulb, which is to be exhausted. A comparison barometer is placed at *v*, and a measuring rod to read off barometric heights is fixed at *w*. The arrangements at *d*, *e*, *f*, and *g*, relate to a mechanical method of counting the number of times that the supply vessel has been let down to be replenished.

Mr. Gimingham has also suggested[3] a mechanical mercurial pump with valves.

A five-fall Sprengel pump, of simpler construction, and jointed with India-rubber tube joints, is used by the Thomson-Houston company, in their factory at Lynn, Massachusetts. The Anglo-American (Brush) company have also used a modified five-fall tube in their works at Lambeth. Another multiple fall pump has been patented by Mr. Donkin.[4]

Dr. L. von Babo[5] described an ingenious method of making the Sprengel pump supply itself with mercury, by the device of connecting it to a water aspirator, worked by a constant stream of water. This aspirator drew in air and mercury at the lower part of the pump, and lifted it up through a narrow tube to a height above the level of the mercury in the supply vessel. Incidentally, this method has the advantage, apparently not noticed by von Babo, of enabling the full tube to be considerably shortened; it has the disadvantage of exposing the mercury to water vapor during a part of its circulation.

Macaluso[1] proposed the addition of a Mariotte's flask, to regulate the flow of mercury, thereby avoiding the need of having a movable reservoir.

Rood,[2] in 1880, described several details of some novelty; an iron valve in the bottom of the supply vessel, capable of fine regulation by a screw, served to determine the rate of flow of the

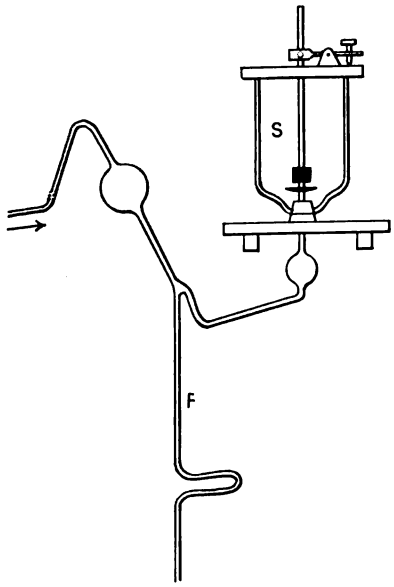

Fig. 24.

Rood's Pump.

mercury. Immediately below the supply vessel, the mercury entered a vacuum bulb (see figure 24), designed to free the mercury from air and moisture, the mercury dropping at once to its lower part, which should be level with the point where the curved supply tube joins the fall tube. This bent tube, about 20

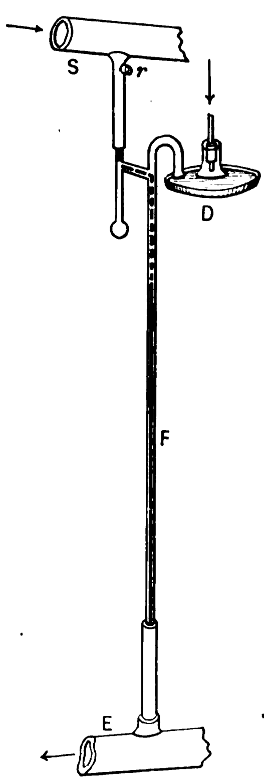

Fig. 25.

Edison Pump (1885).

centimeters long, after descending gently, ascends about 4.5 centimeters; it is made of about the same diameter in the fall tube. The fall tube, as in Mees's pump, is provided with bends. Rood also described a modification of the McLeod gauge. His pump was so mounted that all parts of it could be heated by means of a Bunsen burner. Great importance was attached by this experimenter to this point; as it appeared that much higher exhaustion was thereby attained.

In 1882, Hannay[3] proposed to replace the mercury by a fusible alloy of lead, bismuth, and tin, melting at 94°; by this means it was thought that the necessary imperfections arising from the pressure of mercury vapor would be avoided.

The Sprengel pump employed by the Edison company (New York, 1885) in the manufacture of glow lamps, has a simple fall tube cemented (as shown in figure 25) at its lower end into an iron tube, E, which carries away the ejected air and mercury from a series of such pumps. An iron supply pipe overhead feeds the pumps. Strong sulphuric acid placed in a shallow-glass vessel, D, is used for drying.

CLASS IIa.—SHORTENED DOWNWARD-DRIVING PUMPS.

Stearn,[4] in 1887, working in conjunction with Swan at the problem of perfecting the incandescent lamp, devised a shortened Sprengel pump. It is obvious that the column of mercury in the

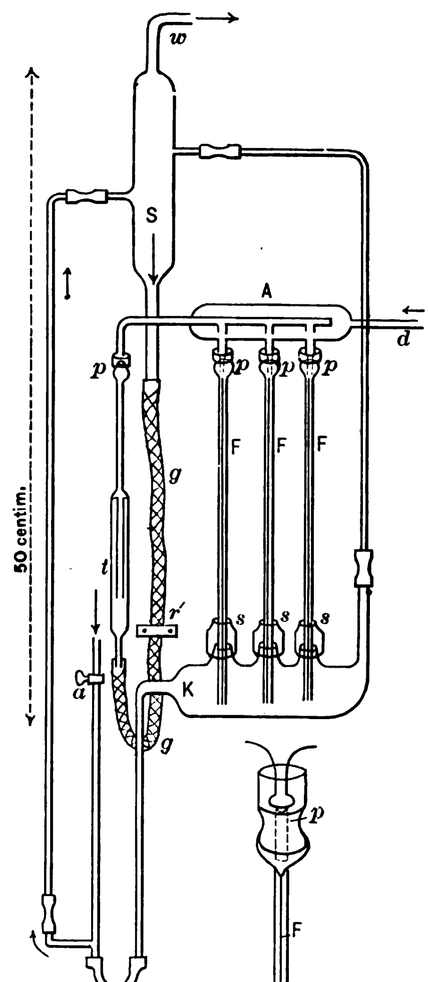

Fig. 26.

Nicol's Pump.

Sprengel fall-tube stands, during the later stages of exhaustion, at about 76 centimeters height, simply because the difference of pressure between the space inside the tube and outside it is about equal to one atmosphere. By removing a portion of the external pressure, the fall-tube may be shortened to any desired extent. Accordingly Stearn applied an auxiliary pump, not at the top as Sprengel had done, to accelerate the early stages of exhaustion, but at the bottom; the collecting chamber, K, being for this purpose closed, and put into communication with the auxiliary pump. Stearn's pump has undergone various modifications; in a recent form[5] there are three fall-tubes of only about 10 inches length, completely enclosed in a partially exhausted chamber. In this pump there are also means provided for carrying up the mercury

from the collecting vessel back to an upper supply-vessel by closing certain taps and opening others which admit the atmospheric air. By this means an extremely small quantity of mercury is made to do duty again and again; and the exhaustion is rapid, because with such short fall-tubes there is less liability of the air-bubbles to stick in the fall-tubes. The action of the pump is made automatic by giving a periodic motion to a three-way cock, which puts a lower receiving chamber alternately in connection with the atmosphere and with the partial vacuum of the

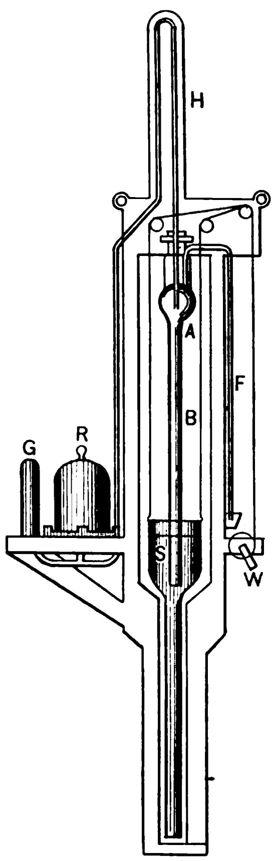

Fig. 27.

Mile's Pump.

auxiliary pump. Stearn has embodied sundry other modifications in patent specifications.[1]

A compact modification of Stearn's pump has been devised by Mr. Swinburne,[2] who has also tried an inverted Sprengel pump.

The most recent shortened Sprengel pump is that of Dr. W. W. J. Nicol, described before the British Association at Manchester in 1887. Its arrangements are depicted in figure 26. The principle of its automatic action is identical with that of Von Babo, an auxiliary water dropping air-aspirator (not shown in the figure) being employed to draw in air at the aperture A, regulated by a tap. This air draws up the fallen mercury in drops, through the return tube, Z, on the left, and returns it into the supply chamber, S, at the top, whence it passes downward through a rubber tube, squeezed between the jaws of a regulating pinch-cock, X, and rises through an air-trap, *t*, into the pump-head. The distributor is simply a horizontal glass tube, sealed into the pump-head, and pierced with small holes above the openings of each fall-tube. (This form of distributor originated independently with Mr. J. T. Bottomley and with Mr. Proctor.) The fall-tubes, F, F, F, are connected to the pump-head in the following manner. Below the pump-head are sealed, on short pieces of glass, tubing of at least five millimeters bore. These are provided with small flanges, and drawn out conical below, so that they can be pushed very tightly through small India-rubber plugs, *p*, *p*, *p*, which are firmly fixed in mercury cups. These mercury cups, which are strangulated, so as to nip the rubber plugs, are sealed to the fall-tubes. The lower ends of the fall-tubes pass into the collecting vessel, K, through simple packings, *s*, *s*, *s*, of rubber tube. The arrows show the course of the mercury. The tube, *d*, leads to the drying apparatus, and to the vessel to be exhausted. This pump can, of course, be used for exhausting only, not for collecting the gas for analysis. The entire height of the apparatus is less than one meter. A very small quantity of mercury—only 800 cubic centimeters—is required. The entrance of water-vapor at S or *a* is prevented by the use of tubes containing calcium chloride. These pumps are now manufactured for sale by F. Müller, successor to Dr. Geissler, of Bonn.

CLASS III.—UPWARD AND DOWNWARD-DRIVING PUMPS.

The earliest example of a pump which drives the air up one barometric column and down another, is the remarkable pump devised by Professor J. Mile,[3] of Warsaw, in 1828. This pump is described by its inventor as a hydrostatic air-pump without cylinders, taps, lids, or stoppers. The description, as will be seen by figure 27, is literally true. The mercury is raised in the barometric tube B, and pump-head, A, by lifting an external cistern, S, of mercury by means of a winch, W. The rising of the mercury first cuts off communication with the vessel to be exhausted by entering the mouth of the exhaust-tube, which is sealed in through the pump-head; and on further rising it expels the enclosed air through a narrow tube, F, sealed in at the top, which bends over to the right and terminates below in a cup of mercury into which its open end dips. This exit-tube and cup constitute a barometric trap, for when the supply cistern is lowered the air cannot return, the mercury rising in the tube, F, to a height depending upon the degree of internal rarefaction. To prevent the mercury from being forced into the vessel that is to be exhausted, the exhaust tube is prolonged overhead to a height exceeding that of a barometric column. The total height of this pump is, therefore, necessarily, about nine feet. It may be looked upon as a sort of Swedenborg pump, the two valves that opened inwardly and outwardly into the pump-head being replaced by barometric air-traps. With such a pump, properly used, a fairly high degree of exhaustion ought to be possible. Strange to say, this pump appears to have fallen into utter oblivion, and its useful features have been several times re-invented.[4]

The use of a second barometric column, down which the air is expelled from the pump-head, is generally attributed to Professor

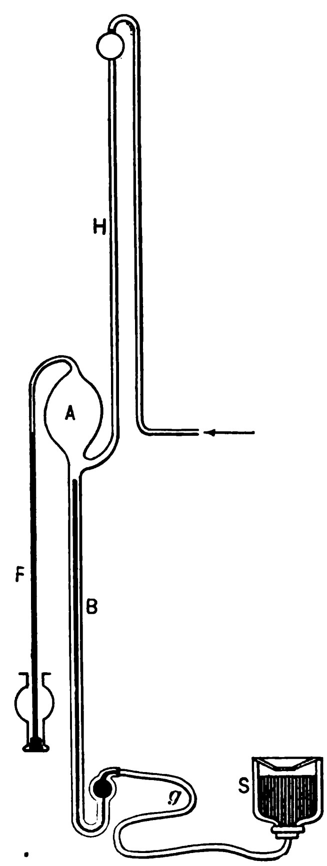

Fig. 28.

Toepler's Pump.

Toepler,[5] of Dresden, whose form of pump is shown in figure 28. Save in the use of a flexible rubber-tube, and in the manner of bringing the exhaust tube to the lower side of the pump-head,

5. Toepler. Ueber eine einfache Barometer-Luftpumpe ohne Hähne, Ventile, und Schädlichen Raum. "Dingler's Polytechnisches Journal," clxiii., p. 426, 1862.

this is identical with Mile's pump. A pump of similar form is sometimes attributed to Mendeleeff; but the writer has been unable to verify the reference. This pump has many of the advantages and disadvantages of the Geissler form of pump. It requires either the tall overhead tube or else an automatic valve. The exit tube, F, is more liable to fracture than any part of the Geissler pump. But, as there are no taps to get out of order, a higher degree of exhaustion can be attained than with any three-way tap arrangement opening into the outer air. There is no need even for any other gauge than the pump itself; for, as Toepler[1] has shown, the degree of exhaustion can be measured (as in the McLeod gauge) by raising the mercury in the pump-head to a marked point on the narrow tube just above the pump-head, so as to compress the residual air into the top of the narrow exit-tube, and then reading off the volume and the pressure of the same, and making the required calculations. It possesses this obvious advantage, that the last residue of air in the pump-head are swept down the tube F, by the mercury that falls over the bend—"Sprengelized" over, one might almost say. In fact, if it were not the case that this pump antedates both Geissler's and Sprengels', one would be disposed to regard it as a combination of the Geissler and Sprengel pumps.

(To be continued.)

ABSTRACTS AND EXTRACTS.

ELECTROLYSIS OF IRON SALTS.

BY ALEXANDER WATT.

(Continued from page 66.)

Ammonio-Citrate of Iron.—A solution of this salt was prepared by first dissolving recently precipitated carbonate of iron in a strong and hot solution of citric acid; the solution was then allowed to cool, when liquid ammonia was added, and the solution was then ready for use. With the current from five small cells a copper plate received a bright silvery deposit of iron immediately after immersion, and maintained this character for some time; but, owing to the anode not becoming freely dissolved, the solution eventually yielded its metal very slowly.

Ferrate of Potassa.—A deposit of iron may be obtained from a solution of this salt, by using a moderate current, but the liquid soon decomposes with the formation of peroxide of iron.

Sulphate of Iron and Sulphate of Magnesia.—For obtaining electrotypes of iron, MM. Jacobi and Klein first deposit a film of copper upon lead or gutta moulds in the usual way, and after well rinsing they are at once placed in a bath composed of sulphate of iron 139 parts, sulphate of magnesia 123 parts. These are dissolved together in hot water, and a little oxalic acid, as also some iron shavings added. The solution is kept in a well-stoppered bottle or carboy, in its concentrated state, and when required for use is diluted with water until its solution has a specific gravity of 1.155 (water being 1,000). In working this solution oxide of iron forms on the surface of the liquor, which must be skimmed off with some of the solution and shaken up in a bottle with a little carbonate of magnesia, and after settling the clear liquor is returned to the bath. The iron deposited from this bath is very hard and brittle, therefore the electro deposit must be carefully handled when separating it from the mould. The copper is removed from the surface of the electrotype, either mechanically, or by dipping it in strong nitric acid.

Ferrocyanide of Iron.—The following solution, devised by Boettger, for coating engraved plates, is probably the only cyanide preparation of any practical value:—Ferrocyanide of potassium 10 grammes, Rochelle salt 20 grammes, are dissolved in 100 cubic centimeters of distilled water. To this is added a solution composed of persulphate of iron 8 grammes, dissolved in 50 cubic centimeters of water. A solution of caustic soda is next added, drop by drop, with constant stirring, until a perfectly clear liquid is obtained of a light yellowish color. This solution, which would have little action upon an iron anode, would require to be constantly strengthened by the addition of concentrated liquor.

Protonitrate of Iron.—A solution of this salt yielded a black deposit of iron in a state of fine division, interspersed with glistening particles of the metal palpable to the touch. A quantity of nitrate of potash was next added to the solution, when at first there was a slight disposition for the metal to go down in the reguline form, but after a few seconds' immersion the plate again blackened, and in less than a minute it became thickly coated with a gelatinous film, covered with hydrogen bubbles of about the size of mustard seed, which remained on the plate for at least half an hour, being coated with a thin rusty film. On leaving a fresh plate in the solution for about an hour, nearly the whole of the iron was thrown down in the form of a black or greenish-black gelatinous mass, which oxidized with great rapidity. A solution of the protonitrate was next made by the battery method, by passing a current from five small Daniell cells through a sheet-iron anode, suspended in a very dilute solution of nitric acid, the circuit being completed by a carbon cathode. The liquid being a good conductor, the electrolytic action was very energetic, and the iron anode became rapidly dissolved, and in less than half-an-hour metallic iron, in the form of granules, was deposited upon the carbon. A copper plate was now substituted for the carbon, which at first received a dark gray metallic film, but in the course of a few moments the deposit assumed the form of a black gelatinous mass, which subsequently oxidized, forming a bright orange-yellow powder.

Double Sulphate of Iron and Potash.—A bath was prepared from a mixed solution of the respective salts, the iron salt being in excess. With three cells of the small Daniell battery, arranged in series, a fine white and very bright deposit was obtained upon a copper plate immediately after immersion, and the deposition proceeded very uniformly for half-an-hour, when the deposit became somewhat streaky; this was remedied, however, by adding more sulphate of potash. Deposition took place very freely, and the anode was considerably dissolved in the course of an hour. This is undoubtedly a very good electrolyte for the deposition of iron, and does not appear, if faintly acid, to oxidize so freely as the ammonio-sulphate solution.

Further Experiments with Persalts of Iron.—In my first paper I gave the results of some experiments with solutions of perchloride and persulphate of iron, in which I was unsuccessful in obtaning deposits of metallic iron. Having recently electrolyzed some other persalts of this metal with somewhat more favorable results, I determined to renew my experiments with the perchloride and persulphate with a view to ascertain if it would be *possible*, under other conditions than those which governed my former trials, to deposit metallic iron from solutions of these salts. In treating the pernitrate as explained in the last paper I succeeded in obtaining copious deposits of metallic iron in a highly comminuted condition, thereby proving that the electro deposition of iron from a persalt (albeit not in a reguline form) is possible. Gore, in his "Art of Electro-Metallurgy," page 245, states that "solutions of persalts of iron yield no metallic deposit, but are reduced to protosalts by the passage of an electric current." That this statement is not correct I will now endeavor to prove. In the first place, a moderately strong solution of pernitrate of iron yields freely a black deposit of metallic iron, which may be collected, as I have shown, and possibly employed in pharmacy. Further, I obtained a reguline metallic coating of iron upon a strip of sheet copper from a solution of the peroxalate of iron. This latter result led me to believe that if the proper condition of the electrolyte could be obtained it was probable that solutions of all persalts of iron would yield metallic deposits. To determine this I prepared a sample of perfectly pure hydrate of the sesquioxide of iron, which was carefully washed and employed in a moist state. With this I formed saturated solutions of perchloride and persulphate respectively. I then determined to try if I could obtain a metallic film upon a copper cathode from a very weak solution of the perchloride (1 drachm of concentrated solution to 3oz. of water) with the current from five small Daniell cells in series, and was pleased to find that under these conditions a film of metallic iron began to form immediately, and in a few moments the plate was covered with a fairly bright deposit of the metal; after awhile, however, the film became blackish at the lower corners. A solution of the persulphate of iron in about the same proportions was next tried with three cells, when a bright deposit of iron at once took place at the corners and lower edges of the plate, which gradually extended upwards in the form of a horseshoe, which character it maintained until the plate was withdrawn. I have frequently noticed that some weak solutions of iron—especially *very* dilute solutions—yield deposits of this form, the metal positively refusing to coat the upper portion of the immersed surface; on the other hand, instances frequently occur, not with iron alone, but with some other metallic solutions, in which the film, while absolutely refusing to form upon the lower surface of the cathode, appeared only on the surface nearest the top of the liquid. Being thus far successful with the perchloride and persulphate solutions, I next tried a very weak solution of the pernitrate. In this trial I was less successful, but when the cathode was briskly agitated in the bath a greenish, non-adherent film was obtained, which, when dried and removed from the plate, was attracted by the magnet. It was metallic iron, therefore, but only in a semi-metallic state until dried. Having thus proved that iron *can* be deposited from solutions of its persalts when the proper conditions have been arrived at, I will now proceed to describe some futher experiments which have recently engaged my attention.

Peroxalate of Iron.—A solution of this salt was prepared by dissolving freshly precipitated hydrated sesquioxide of iron in a hot and strong solution of oxalic acid. The hydrate entered into solution very freely, forming a greenish-yellow liquid. The current from five small Daniells was used, with an iron anode and copper receiving plate as before. Shortly after immersion the cathode became coated with a metallic film of a gray color.

After a few minutes' immersion a gray non-metallic pulverulent deposit rested upon the plate, which was easily brushed off, while a similar powdery film, but of a yellow color, appeared on the immersed portion of the anode. In a short time the liquid became turbid, and a yellowish deposit was subsequently found at the bottom of the vessel.

Sesquicitrate of Iron.—A bath was prepared from this salt by digesting freshly precipitated and moist hydrated sesquioxide of iron in a hot and nearly saturated solution of citric acid; when cold the solution was diluted with about twice its bulk of water. Five Daniells were employed, when a strip of sheet copper received a deposit of iron soon after immersion. The film, however, was neither so bright nor of so good a color as that obtained from the protosalt.

Sesquiacetate of Iron and Acetate of Soda.—A solution of the sesquiacetate was first formed by dissolving hydrated peroxide of iron in acetic acid with the aid of moderate heat. The solution was next moderately diluted (with about two parts of water), and acetate of soda crystals then added and dissolved in the liquid. With the current from five Daniells, a metallic deposit of iron was at once obtained upon a copper plate, this electrode being allowed to remain stationary in the fluid. In about a quarter of an hour the film—which retained its metallic character—assumed a grayish color, and became blistered all over, showing that the deposit, though reguline, was non-adherent.

Benzoate of Sesquioxide of Iron.—A solution was prepared by dissolving freshly precipitated hydrate of peroxide of iron in a hot solution of benzoic acid; this acid, being very sparingly soluble, even in hot water, yielded but a very weak solution, so it was resolved to use it while still warm. The solution was a very bad conductor, and no deposit could be obtained with five Daniells, while the cathode was stationary. When this electrode was briskly agitated in the solution a slight metallic film appeared, on the upper part of the plate only. There was a moderate evolution of gas.

Benzoate of Protoxide of Iron.—A solution was formed by dissolving recently prepared carbonate of iron in a hot solution of benzoic acid. As in the previous case the solution was a poor conductor, and yielded its metal only when the cathode—a strip of sheet copper—was briskly moved about in the bath. The same number of cells were used as in the former experiment, and the solution employed hot, but only a trifling film of iron appeared upon the upper portion of the receiving plate.

Ammonio Nitrate of Iron.—This bath was prepared by dissolving iron in cold dilute nitric acid by the action of the current, the operation being kept up until the solution was as neutral as possible, when a little ammonia was added. As is the case with most other nitrates, the solution had little disposition to yield a reguline deposit of metal. A slight metallic film appeared upon the cathode for an instant, but this quickly changed into a black deposit of pulverulent iron precisely similar in character to that obtained from the persalt. This black film, which soon became very thick upon the plate, was slimy to the touch, and consisted of metallic iron in a highly comminuted state, interspersed with bubbles of hydrogen, some of which were of considerable size, and retained their position upon the plate for many seconds—probably half a minute. The black deposit was washed off the plate into a glass containing hot water, and a fresh plate immersed in the liquid, and allowed to remain stationary for about two minutes, by which time it received a copious deposit of the same character as before, which was afterwards removed by washing, as in the previous case. Several plates were coated with the black deposit in this way, and the finely-divided metal afterwards well washed, drained upon a filter, and dried. The black powder thus obtained was then placed upon a sheet of paper, and treated with the magnet in the following way:—A piece of thin paper was laid over the poles of a small horseshoe magnet—to prevent the finely-divided metal from attaching to the magnet itself—which was then drawn across the metallic particles, but at a short distance from them, when they rapidly ascended and clung to the paper, and to each other, forming a metallic fringe of about a quarter of an inch in depth and about an inch in length. The fine metal, thus suspended, was then conveyed to a second piece of paper, and the magnet withdrawn, when, of course, the metallic particles became dislodged and fell upon the paper. The remaining atoms of metal were collected and transferred in the same way, when it was found that the first piece of paper, upon which the fine metal had been placed was perfectly free from particles of any kind, showing that the black deposit obtained from the solution in question consisted solely of metallic iron. It should be mentioned that when these black deposits of iron, after being drained from surrounding water, are dried slowly, a film of oxide forms upon the surface of the particles, giving the dried material a reddish tint. This does not, however, prevent the magnet from attracting them. In this experiment the anode, which was much worn, remained exceedingly bright.—*The Electrician* (London).

(To be continued.)

THE SOCIETY OF TELEGRAPH ENGINEERS AND ELECTRICIANS DISCUSS THE ALTERNATING SYSTEM.

At a recent meeting of the Society of Telegraph Engineers and Electricians two papers were read dealing with the subject of alternating current converters or transformers and the distribution of electricity by means of these appliances. The first of these papers, by Mr. Kapp, we reproduce in our present issue. The second was by Mr. J. Kenneth D. Mackenzie, and in it the question of distribution was treated from a general point of view, including dynamos, mains, transformers, and other matters which may best be described as coming under the title of general principles and administration of electric light stations. These two papers are the first on the subject which have been submitted to a scientific society in England. Information in connection with transformers has been carefully withheld by the makers and users of such apparatus—a state of things probably due to the pending litigation on transformers. The paper of Mr. Mackenzie was specially interesting, as this gentleman has had much practical experience in the working of converters or transformers. The author distinguished between polar and non-polar transformers, the first being of the type of the original Rumkorff induction coil, whilst the latter are developments of the well-known Faraday ring. Messrs. Gaulard & Gibbs were the first to take up the subject on a commercial scale, employing polar transformers which had either a movable core or a fixed core provided with a movable gun metal shield, by which means the E. M. F. and the secondary circuit could be adjusted; but these devices were only adopted in their first experimental installations, when it was thought desirable to have means for readily adapting each transformer for the work it had to do. For permanent installations, however, where the conditions of supply could be settled beforehand, Messrs. Gaulard & Gibbs adopted the non-polar type of transformer, and introduced a series of improvements, the object of which was (1) reduction of electrical resistance, (2) maximum induction with a minimum weight of materials, (3) perfect symmetry between the primary and secondary circuits, and (4) an equal weight of copper in the two circuits. Referring to the manner of coupling up the transformers in a general system of supply, Mr. Mackenzie stated that transformers might be worked in various ways. If in series, the lamps fed from each transformer must also be placed in series, and two years ago he had jointly with Mr. Bernstein, made some experiments, which, so far as regulation went, were perfectly successful. The primary current was adjusted to the same strength for each experiment, and those lamps which were not required were simply short-circuited. He found it possible to short circuit the whole of the secondary without perceptibly increasing the current, and without any danger of overheating. The difficulty he found was not in the transformers, but in the dynamo. He found it almost impossible to maintain the current of the dynamo constant under varying loads, and considered improvements in this direction very desirable. Transformers might be worked in simple parallel arrangement, as is now customary, or they might be worked on the three-wire system, or on the parallel network system, both the primary and secondary mains being all joined in two networks. This is the system employed by Mr. Westinghouse in America. As regards the mains, Mr. Mackenzie is in favor of overhead wires, these being more easily insulated; but he recommends that they should be suspended from bearers, consisting of copper or phosphor bronze cables, by insulated hangers at about every yard. In certain localities the bearers might be steel cables; but in large towns copper or phosphor bronze would be preferable, as not so liable to destruction from atmospheric influences. The bearers should be designed so as to have at least a ten-fold margin of safety against breakage. One of the difficulties he found in connection with bearers was, that on long circuits they became charged with an alternating potential by induction from the mains, and a considerable shock would be felt by touching any of the bearers, although they were insulated from the main. In the early days of the Grosvenor Gallery installation, some difficulty was experienced from the mains by their inductive effect on the telephone wires, and owing to the number of complaints received from telephone subscribers, the company instructed him, in conjunction with Dr. Hopkinson, to investigate the subject, and report on the best method to remedy the evil. The installation was then worked on the series system, and the evil was removed by the simple device of running the return main parallel to the outgoing main over the whole district. By this means the effect of the current on the telephone wires in one main was neutralized by that in the other main. When the cables are placed underground the author suggests the employment of an earthenware channel, with a cover made as nearly as possible watertight. Within the channel are placed shelves of paraffined wood, on which the conductors rest, and at stated intervals drainage holes are provided for getting rid of water which might find its way into the channel. He does not advocate the use of lead covered cables. In the installation at Aschersleben

these cables were used both for the supply and the distributing mains; but it was found that the lead was destroyed by sparks due to a static charge, the cable forming a condenser, and these cables were ultimately abandoned. At the installation in Tours some difficulty was also experienced with underground cables; but since these were laid in earthenware troughs, similar in construction to those suggested by the author, no further difficulties were met with. The author also showed a plan of Port of Spain, in Trinidad, for which he had designed an electric light installation, there being about 20 miles of circuit.

In dynamos for alternating currents considerable improvements have been made during the last few years, the most remarkable of these being the adoption of iron in the core of the armature. In certain cases Mr. Mackenzie recommends the employment of a low tension dynamo at the generating station, and transforming the current from it by a large transformer into one of high tension, which is sent into the supply mains; but he is opposed to the system of employing dynamos of excessively large dimensions. In this connection he adversely criticised the proposal of one London electric light company to erect dynamos having armatures 42 feet in diameter, and requiring 5000 i. h. p., supplied by quadruple expansion marine type condensing engines. He thinks it far safer to employ a number of dynamos coupled in parallel, the capacity of each dynamo not to exceed about 10 per cent. of the total capacity of the station. There is no difficulty in working alternate current dynamos in parallel, and he has, in fact, done so with Siemens' machines at the Grosvenor Gallery; but he found that the synchronism between the machines was not very stable, and easily disturbed by external influences. With modern machines this difficulty might not prove so great. A diagram of the Kingdon dynamo was exhibited. The peculiarity of this machine is that both the field magnets and the armature form part of the same structure, and that the movable portion of the machine contains iron only, but no wire. Briefly described, the machine which the author and Mr. Kingdon are now building, and which is to absorb 50 h. p., consists of a circular yoke ring, 10 feet in diameter, having a number of short radial magnet cores projecting inwards. Between these revolves the armature wheel, which might conveniently also form at the same time the fly wheel of the engine. Every alternate core is wound with exciting wire, so as to produce north and south poles alternately on the inner end, whilst over the intermediate cores are placed the coils in which the alternating currents are generated. The revolving part consists of a wheel carrying on its outer circumference a number of soft iron armatures, the width of each being such as to span over the inner ends of two adjacent magnet cores. When the wheel is revolved, these armatures seem to carry north and south lines alternately, through the cores on which the armature wire is wound, and by this means alternating currents are generated.

Regarding the placing of transformers, Mr. Mackenzie is of opinion that the provision of a small transformer for each house is only admissible when the number of consumers is small; but for a general supply and for permanent work the transformer should be kept out of the house, and a sufficient number should be installed throughout the district, so that the maximum distance of any lamp from the nearest transformer should not exceed 120 yards Great care is to be taken in the wiring of houses, and he deprecated the system of utilizing the existing gas fitting for the attachment of lamps. In his own experience, when connected with the Grosvenor Gallery installation, and it was worked on the series system, he has known as many as eight houses plunged into darkness owing to short circuits occurring between the gas fittings and the electric wires in the first and last of these houses. If for reasons of economy it is necessary to use gas brackets, he recommends that their connection with the gas pipes should be interrupted.

The discussion on the papers read by Mr. Gisbert Kapp and by Mr. J. Kenneth D. Mackenzie was opened by Professor Ayrton, who agreed with Mr. Mackenzie that considerable credit was due to Messrs. Gaulard & Gibbs for drawing attention to, and practically working out, the method of distributing electricity by secondary generators. One reason why the importance of this system was not at first recognized was, perhaps, to be found in the fact that the measurements of the efficiency of the earlier apparatus were made in a crude and inaccurate way. Thus the potential difference at the terminals of the transformer was measured by a high-resistance dynamometer, and the current was measured by a similar instrument with a low-resistance, the product of these readings being considered as giving the energy expended in watts. Both authors seemed to consider it impossible to work the primary coils of the transformers in series when there was a varying resistance in the secondary, but by a method analogous to compounding a dynamo, he thought that this difficulty could be overcome. This idea of compounding had occurred to his colleague and himself some time ago, and they had attempted to solve the problem mathematically, but as the analysis became very complex they gave it up, and were proceeding to treat it practically when the same idea was patented by Zipernowski, and they had not therefore proceeded further with the subject. He was very glad that the idea of magnetic lag as distinguished from that due to Foucault currents, was gaining credence, as Professor Perry and himself had drawn attention to it years ago and been laughed at for their pains. But now, thanks to the experiments carried out by Professor Ewing, its existence was universally admitted. He had said something about wrong methods of measuring the efficiency of transformers, he would now point out correct methods of measurement. There was only one way of measuring the power given to a circuit in which self-induction took place, and this, which depended on the use of a quadrant electrometer, had been devised simultaneously and independently by Professor Fitzgerald and himself, and might be described as follows: Let P and Q be the terminals of an inductive resistance through which an alternating current is being passed by a dynamo. Let a non-inductive resistance Q S be put in series with P Q. Connect the quadrants of the electrometer to S, the other two to Q, and the needle of the electrometer to P, and observe the steady deflection. Secondly, disconnect the needle from P and join it to Q, and take a fresh reading. The difference between the readings thus obtained is a measure of the power expended in the circuit in watts. This method of measurement was theoretically perfect, but it depended for its truth on the assumption that the law of the electrometer, as given by Clerk-Maxwell, was the correct one. But with most electrometers in actual use he had found that this law was not satisfied, and he should present a paper on the subject on a future occasion. It has consequently been necessary to determine the efficiency in some other way, and in their experiments they had adopted the plan of measuring by a calorimeter the heat developed in the transformer, and had obtained in this way very fair results. On comparing the results thus obtained with those given by adopting the same method as Messrs. Gaulard & Gibbs had done in their earlier experiments, they found that figures given by the latter plan were in certain cases three times too great. Mr. Kapp had described two methods of rendering transformers safe, but a simpler plan than either was to connect one terminal of the secondary core to earth, which would not only prevent this coil acquiring a dangerous potential, but would also prevent workmen or others getting a shock from the electrostatic capacity of the coil, which would not be the case with the other methods mentioned by Mr. Kapp.

Captain Cardew remarked that the chief theoretical novelty in Mr. Kapp's paper was the method of calculating the power lost by heating; but he did not completely agree with Mr. Kapp's reasoning, which depended on the hypothesis of a molecular friction. This did not, however, appear to him completely satisfactory, as he was inclined to look on a molecule under cyclic magnetic changes as in the condition of a spring, in which, although the power given out might not be altered, yet lagging might occur. With reference to the danger of alternating current installations, this must always be very great when a potential of upwards of 2,000 volts was employed, as with faulty insulation all the conditions were favorable to a breakdown. He had waited a long time for the appearance of some method of reducing the risk, and had finally invented what he might call an electric trap himself, which had been described in Mr. Kapp's paper.

The foil mentioned by Mr. Kapp, was, however, of aluminium, and not of platinum, the lightest and not the heaviest of metals. The plan of putting one terminal of the secondary to earth as advocated by Professor Ayrton, increased the risk of a breakdown, as the strain on the insulation, which must be always more or less imperfect, was greatly intensified. With regard to Mr. Kent's device, he could only say that as a customer, or as a dynamo manufacturer, he should be perfectly satisfied with it, but as a supplier of electricity, he would prefer to adopt something else.

Mr. Bernstein said that in a large installation on the alternate current system the question of insulation became very serious, and it would therefore be advantageous, other things being equal, to work the transformers in series, as the average difference of potential was on this plan reduced to one-half of that obtaining with the parallel system of distribution. Moreover, the potential difference between the terminals of the primary coil of the transformer would also be reduced to perhaps one-fortieth of its value on the other system, and as the insulation of a transformer cannot be made very heavy without sacrificing the efficiency of the apparatus, this reduction of the potential difference greatly diminished the risk of a breakdown. With regard to Mr. Kent's safety device he thought it would work well, but there was such a thing as leading a current into temptation, that was to say, that if a current was given a chance to go to the ground it would not hesitate to take advantage of it. Professor Ayrton had mentioned the plan of connecting a terminal of the secondary to earth, and he would remark that when he had first brought out the contact-plug used in his system of incandescent lighting, Professor Forbes had pointed out that the same device could be used to connect the secondary coil of a transformer to earth, and would render it absolutely safe. The contact-plug consisted of a mixture of mercuric oxide and carbon, which had normally a very high resistance; if, however, through any considerable rise of potential a large current was forced through the plug, the

oxide was instantaneously reduced to metallic mercury, and the resistance practically eliminated. These plugs had been in operation in installations of incandescent lighting on the series system of distribution for over a year, and in that space of time had never failed to act.

After some remarks from Mr. Atkinson, Professor Fleming stated that he had in 1885 made some experiments with the Zipernowski transformers exhibited at the Inventions Exhibition, which were employed in running 200 16 c. p. lamps, the potential difference used in the primary being 1,000 volts. To prevent the danger, first pointed out by Dr. Hopkinson, of shocks from the electrostatic capacity of the secondary coil, he had proposed connecting one terminal to the earth, but on publishing the idea Professor Elihu Thomson had written claiming that he had devised this plan previously, and on this Professors Ayrton and Perry wrote, pointing out that they had anticipated Professor Thomson. Mr. Zipernowski had attempted the compounding of the transformers, and the results were fairly satisfactory. To determine the efficiency of the system they had used a couple of very large wattmeters which had a very low self-induction, the major portion of the fine wire coil being merely external non-inductive resistance, and with the results thus obtained the curve of efficiency shown on the wall had been plotted. Professor Ayrton had pointed out that the results thus obtained must be inaccurate, but it would be interesting to determine the amount of error. There was no question now as to the results of the magnetic lag. There was consequently a modification of the magnetic resistance of an alternating magnetic circuit analogous to that of the electrical resistance of an alternating electric circuit. The theory of transformers was in some respects simpler than that of the dynamo, as there was no air-gap to be taken into account; experiments should, however, be made on the permeability of iron at different periodicities.

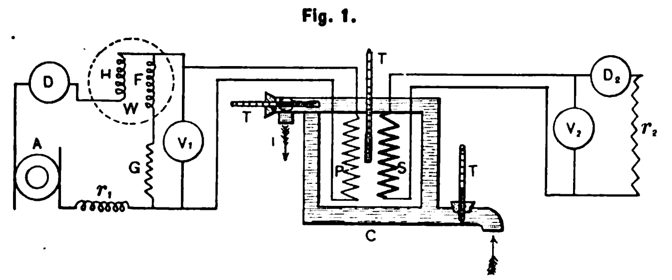
Mr. Crompton, as a commercial man, who was thinking of going into transformer business, wished to know from Mr. Mackenzie what the total efficiency of the whole system was. With regard to other methods of distribution, he could give figures for the efficiency of the system, from the coal in the furnace to the lamps, and if Mr. Mackenzie would do the same for the alternating current the two systems could be compared.

At the conclusion of Mr. Crompton's remarks the meeting was adjourned.

ADJOURNED DISCUSSION.

The adjourned discussion on transformers and the distribution of electricity by their means was resumed on Thursday, the 23rd ult., by Mr. Lamb, one of the gentlemen who had made calorimetric experiments with the transformer to which Professor Ayrton referred at the previous meeting. Mr. Lamb described the apparatus used, and exhibited some interesting efficiency curves, showing that the true efficiency of a transformer, as determined by the calorimeter, is throughout greater than the apparent efficiency determined by a wattmeter, or by the indications of a dynamometer and voltmeter. Figure 1, represents the transformer enclosed in the calorimeter, by which the true watts were determined. There were also in circuit the wattmeter, *W*, the dynamometer, *D*, and the voltmeter, *V*. The ratio between the reading of the wattmeter and the true watts was given by Professor Ayrton. The curve in figure 2, shows the true efficiency as calculated from

Fig. 1.



the calorimeter observations, and also the values obtained from the wattmeter. and from the product of the readings of the dynamometer and the voltmeter.

Mr. Gordon regretted that so much labor and ingenuity should be wasted on problems connected with alternating currents, because there was no future for them. He himself was one of the first to use alternating currents at the large installation put up by him at the Paddington railway station, and this system is still at work, with satisfactory results; but notwithstanding this success, he had come to the conclusion that the employment of alternating currents is beset with so many difficulties as to make the system unfit for general adoption. One of the objections is the large size of dynamo. He himself has constructed alternating current machines which were larger than any other machine produced up to that time, and although it may be very satisfactory for an engineer to see these huge armatures revolving, it was less satisfactory to the shareholders of the company. A 200 kilo.-watt machine would require an armature 10ft diam., whereas a 100 kilo.-watt low tension continuous current machine could be made with an armature only 16in. diam. Another objection to the system was that the whole of the power must be developed in one machine. He did not think it was possible to couple several alternate current machines together without producing considerable jumping in the lamps, which would, of course, shorten their life. Mr. Gordon exhibited an interesting diagram, showing that in a residential district the maximum number of lamps is only on for an hour and a half each day, viz., from 6 to 7.30 p.m., whilst from one-half to two-thirds of this number is on from 5 or 6 o'clock in the afternoon till 10 p.m. From 10 o'clock to about 3 a.m. the number of lamps alight steadily declines, and from 3 a.m. to 3 p.m. in winter it is only a small fraction of the total number fixed. The uneven rate of consumption is a great difficulty, because

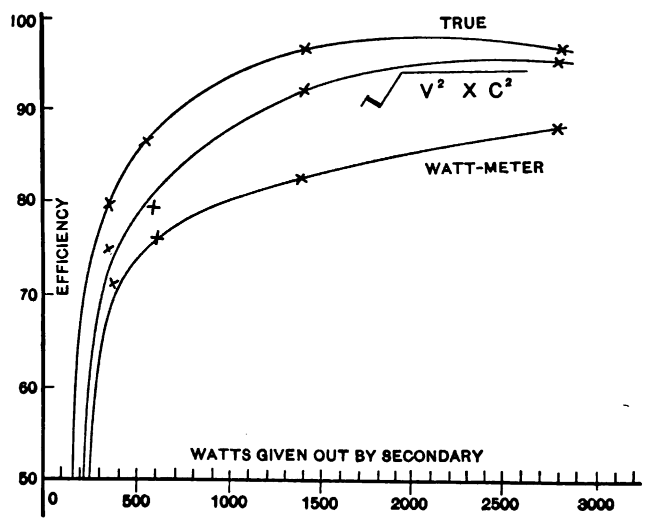


Fig. 2.

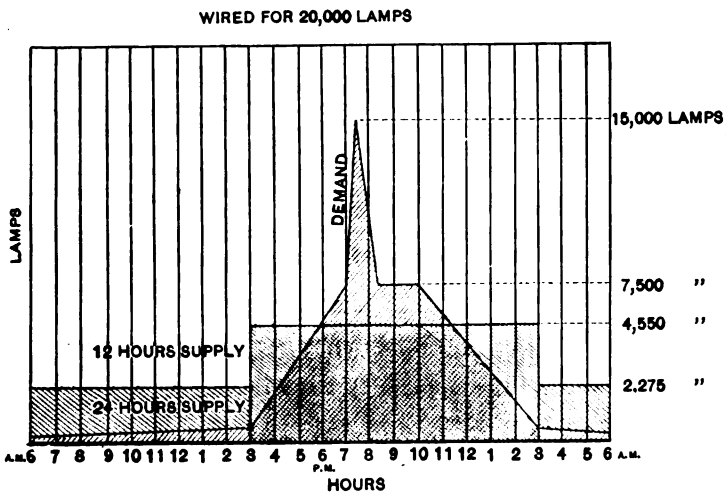
machinery must be provided equal to the large consumption, and the plant is therefore in excess of the requirements for twenty-two hours out of the twenty-four. Now let them see what would happen if they had storage batteries. Assume first of all that they were going to have a moderate amount of storage, and would work their machines for 12 hours. The quantity of electricity for the day was shown by the area of the demand curve; that showed the number of units—and the area of this second curve, or 12 hours' supply, must be the same as the area of this other curve, showing the quantity required for the day. If they had storage and worked their engines for 12 hours, the maximum current need only be a current for 4,550 lamps. The size of the engines, burners, and boilers was fixed by that. Therefore, for 20,000 lamps, with an occasional supply of 15,000 at once, it was not necessary to have, by storage, machinery of greater capacity than 4,550. If, however, they decided to work their engines for 24 hours—which might in some circumstances be advisable—they could then have something much smaller still. By this means small engines and dynamos only are required; but being kept at full work for a longer period, the total output is the same as with a larger plant spasmodically worked, whilst the efficiency is of course much higher. Engineers knew perfectly well that it was uneconomical to work engines much below their power. So convinced was he of the superiority of lighting by batteries, as compared with the direct system, that he was now engaged in putting up a central station at Whitehall place, where it will be possible to do what gas companies are doing, viz., to utilize the waste products. In this case the waste product is exhaust steam, which will be used for supplying hot water to the baths and heating apparatus of the residential chambers for which the central station is being erected. Mr. Gordon, after collecting statistics on the amount of gas lighting done in London, has found that there are about 125,000 gas jets to the square mile.

Mr. Crompton, who followed, spoke in the same strain. He thought Mr. Kapp's paper was rather dry, and he would therefore try to infuse a little life into the discussion by treating it from the commercial side. He did not deny that the transformer system had developed to a certain extent in America, but this was merely due to the fact that Americans would put up with any lighting, no matter how bad. It had also been developed to a considerable extent in London by the Grosvenor Gallery Company, and in this connection he thanked Sir Coutts Lindsay very cordially for being engaged in educating Londoners in the use of the electric light, and teaching them to put up with scintillations instead of good steady lighting. He thought that the clients of the Grosvenor Gallery could not be very fastidious, and it would be very easy for him or any other electrical engineer to satisfy their

demands in the future. As most of them knew, he had carried out central stations in which the transformation from high tension currents of 500 volts had been carried down to 100 volts, usually employed in incandescent lamps by means of four batteries in series. He had data from these installations, and data which were of use. It was no use in such a place as that to discuss the question of management—wages and matters of that kind—but it was of great use to discuss the engineering part of it, that is, the question of which system worked with the least horse-power, with the least first cost in machinery, the least first cost in mains, and the greatest steadiness and regularity and freedom from breaks down. From these points of view he proposed to compare the system of alternating transformers, with the system of battery transformers. At this stage he would remind them of the tremendous leg-up which the alternating transformer system had received from Mr. Westinghouse. Westinghouse was one of the most wonderful men in the world. There was no man like him as an organizer of labor and as an organizer of machinery. Witness his brake. In the face of the most tremendous opposition from the railway authorities he had made his brake almost universal, and he had done that with all these peculiar powers. He was a very rich man, and he had unexampled facilities at Pittsburg, where his most successful lighting had been carried out. But he would tell them that



what Westinghouse had done for the transformer system was exactly what Brush did for arc lighting in England a few years ago. He had turned out from a well-appointed factory complete, well-considered sets of machinery, packed and sent away to any township in America that wanted electric light of a sort. It could be put up in the way that American electric lighting machinery was done—very roughly—on the spot. But the things were so well appointed and so well made in the factory, that they could be erected at small cost, and in sufficiently good rough and ready fashion to suit the American taste. Anybody who had been in America, anybody who knew anything about American installations would confirm what he was saying—that electric lighting machinery in America as made in the shops was perfection; but the putting of it up was such as would not pass muster in the worst of our English installations. That had been the case with the enormous list of transformer machinery that had been carried out by Mr. Westinghouse. Although that was perfectly suited for such countries as America and Australia, countries where rough workmanship and such things did, it was quite unsuited for civilized countries. The moment they brought it into London, the moment that it was no longer a rover, as it was at present, over the tops of the houses, the moment they confined it under the streets, then it lost all its advantages. What were its advantages? Its advantages were that they could put down a station, and they could run wires anywhere they pleased, on account of the peculiar state of the law, and take up a number of customers that otherwise they could not reach at all. But he said that when the taste for electric lighting became more universal, when two in every three people along the line of streets took the light—that such a system of overhead mains and that kind of thing was intolerable; and there must come the day when mains had to be laid, as they had been successfully laid under the streets, and then they would find that the alternate transformer system was out of it as compared with the other. He did not believe that it was possible to work alternate current machines in parallel, and therefore it was necessary to do the whole of the lighting from one huge machine. This entailed a considerable waste of power when the demand for light was small, and therefore he thought that the average efficiency of the system must be exceedingly low. They were told by Professor Ayrton that the transformer he tested had a very high efficiency. That may be so, but what he wanted to know was the efficiency taken commercially, viz., from the coal bill to the money received for the sale of the current. This he ventured to say would be very unsatisfactory to the supplier of the electric light on the alternate current system. He drew attention to the last paragraph in Mr. Kapp's paper, where the author said that his net work of mains would be available for use with batteries if at a future time the change of system could be effected. He thought this showed that the author himself did not believe very firmly in transformers. The speaker had already adopted the battery system in several installations, and found it exceedingly economical. There was no need of employing currents of 2000 volts, as it was quite feasible to light a district a mile away from the generating station by currents of 500 volts, and yet to have comparatively small mains.

Mr. Esson did not think that the author's assumption regarding the curves of electromotive force and current were consistent with actual facts. He doubted that a dynamo which contained iron in its armature could give a true sine curve. This was shown on a wall diagram on which was drawn a true sine curve, and a curve calculated by Mr. Esson for a particular dynamo (figure 4). If, then, the curve be not a sine curve, the graphic method of the author, he thought, became useless.

Professor Perry dealt with the same subject, but came to a totally different conclusion. He thought the current given by any dynamo might with very little error be considered to follow the true sine curve. It was well known that a curve of any shape could be considered to consist of a true sine curve with other sine curves of the second, third, or fourth order superposed. Now the action of the transformer was to smooth down the ripples thus formed, and as this action was the stronger the more marked were the ripples. From this it followed that whatever may be the shape of the pole pieces or the disposition of the iron in the armature, the current passing through the transformer would follow very nearly a true sine curve. The difficulty of employing alternating current machines in parallel he did not think was insurmountable. It would be perfectly easy to contrive an instrument which would permit of the coupling up to be done only when the two machines have come into synchronism, and the same instrument might be used to regulate the power and speed of the engines, so as to maintain the synchronism.

Mr. Mordey could not agree with the author that it would be well to keep the transformers out of the houses, and to employ a proper low tension distributing network. He thought that by doing this one of the great advantages, viz., cheapness in distributing plant, would be lost. He would prefer to give each consumer his own transformer, or at the most to employ one transformer in common for two houses. Referring to the question of lag, he described an interesting experiment which apparently showed that there was no appreciable lag. In the first experiment he had two transformers. The thick wire terminals of the first connected with the dynamo, the fine wire terminals of the same transformer were connected with the fine wire terminals of the second transformer, and between the thick wire terminals of the second transformer would therefore be produced the same potential difference as that given by the dynamo. If now one of the thick wire terminals on each transformer were connected by a short wire, and a voltmeter was inserted between the remaining two thick wire terminals, this would indicate either the sum or the difference of the potential difference existing between each pair of terminals. If there were an appreciable lag the sum would be somewhat smaller than twice the potential difference of the

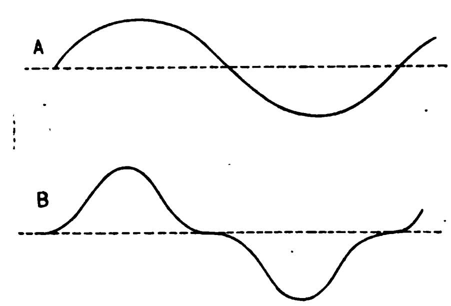


Fig. 4.

dynamo, and the difference would be somewhat greater than zero. If there were no lag the sum would be exactly twice the potential difference of the dynamo, and the difference would be exactly zero. To his surprise he found that this was actually the case, and even when he had coupled six transformers in the manner here described, the total potential difference over the whole series of six was exactly six times that existing between the terminals of the dynamo. This experiment seemed to show that there was no appreciable lag.

Mr. Wright could not agree with the author that the shell transformer was inferior to the core transformer. He himself had adopted the shell type because most of the heat was produced in the iron, and for this reason he thought it wise to place the iron outside.

Professor Silvanus Thompson thought the distinction of transformers into shell and core transformers was not a very definite

one, as it was impossible to say, in some cases, whether a particular transformer belonged to one or the other class. The graphic method of the author was certainly very simple and of practical use, because it enabled engineers who had no special mathematical training to solve problems connected with transformers. Mr. Esson's objection that the curve was not a true sine curve, he could not share. He had already, on previous occasions, expressed his opinion that the transformer is the very best possible apparatus for toning down the ripples in the curve, and altering its shape to that which corresponds to a true harmonic function. He thought that before high pressure service by means of continuous currents could be obtained, it would be absolutely necessary to improve the commutator of the dynamo. Mr. Crompton mentioned 500 volts as the highest pressure he intended to apply. This he thought an insufficient pressure if economy in mains was the object. The reason why Mr. Crompton adopted this low limit was simply that he could not get an ordinary commutator to work satisfactorily with a pressure of 2000 or 3000 volts. All the successful high tension machines had special commutators, but in the alternating system this difficulty was entirely overcome.

After a few remarks from Mr. Evershed and Mr. Kent, the President called upon Mr. Kapp to reply. The space at our disposal does not permit of our mentioning the various points touched upon in the reply, and we must, therefore, limit ourselves to that portion of it which had the greatest practical importance, because dealing with the comparative merits of the rival systems of supply brought forward at the meeting. Referring to the remarks made by Mr. Gordon and Mr. Crompton, the author did not dispute that distribution of electricity by means of secondary batteries was preferable to distribution by transformers; but before they could adopt the more perfect method it was absolutely necessary to have a reliable secondary battery. He himself had not met with such a battery, and if Mr. Crompton could bring one forward he should hail its advent with delight. All the arguments which were used by these two speakers on that evening might with equal reason have been used three or four years ago; but they were not used, simply because the speakers had at that time no confidence in batteries. If a battery could be put on the market which would be as reliable and as efficient as a transformer, and the cost of which would not be excessive, the author himself would be amongst the first to recommend its adoption for central station lighting, and that he did not doubt the ultimate discovery of such a battery might be seen from the concluding paragraph of his paper, where he advised that a secondary network should be laid down in the streets in such a manner as to be available for use with batteries at any future time. Mr. Crompton's objection regarding the inefficiency of transformers when these are worked at low output, was met by the diagram which Professor Ayrton had exhibited on the wall. They would see that even with an output as low as a third of the normal the efficiency was still 85 per cent. It would never be necessary to work transformers below this output, because if the consumption decreased sufficiently they would simply switch off certain transformers on the network, leaving the work to be done by a smaller number, which would then be worked to half or three-quarters their capacity. Great stress had been laid by Mr. Gordon on the fact that the maximum number of lamps was only on for a very short time during the day, and that the plant must, therefore, be very much too large for the supply required during the rest of the time, and also be worked uneconomically. The latter objection, he thought, had been met by some of the speakers, who showed that machines could be worked in parallel, and that it was therefore not necessary to do all the lighting with one huge machine. As regards the other objection, this applied equally to batteries, and where it was even of greater weight, because for equal output batteries were more expensive than engines and dynamos. The author's programme was to adopt transformers and alternating currents for the present, and to retain them only as long as they could not get a reliable battery. If they could get such a battery, he would advocate to discard the alternating current machines and the transformers. This would entail a loss of only 10s. per lamp fixed, which might be taken as the cost of dynamos and transformers; and when they considered that the central station, boilers and engines, the network, the house wiring, and the lamps would remain equally useful after the change, they would see that the loss entailed by the change was really very trifling.

The President then called upon Mr. Mackenzie to close the discussion. Owing to the lateness of the hour the reply was necessarily brief; but *Industries* was favored by Mr. Mackenzie with some notes of his written reply, which he sent to the secretary of the society, and the following is a short abstract: In reply to Professor Ayrton, who had asked whether compound winding of transformers had ever been tried at the Grosvenor Gallery, Mr. Mackenzie said that some experiments had been made with an apparatus consisting of a single coil of fine wire, placed in shunt to the primary of the series tranformer. The coil surrounded a core consisting of a bundle of iron wires, which could be more or less inserted to suit the requirements of the secondary circuit. The results were, however, unsatisfactory, the coils always being burned up after some time, and the idea was finally abandoned. Mr. Bernstein's suggestion of using a fusible contact plug as a safety device the author considered quite feasible. It would not only be cheaper than the apparatus devised by Captain Cardew, but it was also free from the objections which are justly urged against the proposal of putting any point of the secondary circuit to earth. In reply to Mr. Atkinson, the author said that fluctuations in the strength of the exciting current had been observed with the Kingdon dynamo, though these fluctuations were not very great. They were probably due to the cause mentioned by Mr. Atkinson. The author did not intend to convey the impression that the fly wheels of existing engines should be altered to suit the Kingdon dynamo, but that in designing new plant for a central station, the fly wheel of the engine, which is necessary to insure steady running, could be made to form part of the dynamo, and thus combine two functions in one. The object of arranging the machine into various circuits was with a view to cut out certain of these circuits as the consumption diminished, so that the remaining circuits would be worked at maximum efficiency. With reference to Mr. Crompton's question regarding the actual cost of working the Grosvenor Gallery installation, the author thought Mr. Crompton had asked rather too much. Many of his objections against the alternating current system had already been answered by other speakers. There could be no gainsaying the fact that the transformer system had made great headway, and this would never have been the case had it not possessed sufficient merits to place it before all others for the general distribution of electricity. The author himself expected to see Mr. Crompton before long become as warm an advocate of the transformer system as he had many years ago been an opponent of electric distribution by secondary batteries. Professor Silvanus Thompson and other speakers had taken exception to a statement in the beginning of his paper as regards the Faradaic theory. He wished to point out that neither he nor Mr. Gaulard had ever denied the Faradaic theory of induction; but Mr. Gaulard had from the first believed that this theory, as exemplified by Rhumkorff, was not a proper basis for the construction of transformers.

THE ALTERNATE vs. THE CONTINUOUS CURRENT.

The following letter appears in the *Western Electrician* of March 24:

In your issue of March 10, I find reported a paper read before the Chicago Electric Club on March 5th, upon "The Comparative Value of the Continuous and Alternating Current Systems, for the Commercial Distribution of Electricity," by Mr. H. Ward Leonard, in which paper, and in the discussion which followed it, some statements about our system here were made, which I desire to correct.

I do not intend to argue as an advocate of the alternating system: I have done enough in that direction at the electrical conventions. I only wish to correct false impressions which concern me individually as superintendent of this work.

Mr. Leonard speaks of the death of a telephone operator in Pittsburgh. This is simply not so. There has been no telephone operator or any one else in Pittsburgh killed by the alternating system. The instance to which he refers, and which has probably been misrepresented to him, was the stunning of one of the girls in the telephone exchange by a shock from one of the magneto bells used for calling subscribers. Surely Mr. Leonard does not, therefore, desire the telephone taken out of the house as a deadly menace to the lives of our mothers, wives and children.

We have a great many cases where we are operating 100 volt and 50 volt lamps from the same converter, though not necessarily on the three-wire system, but we have run 100 volt lamps on 50 volt converters, by putting the secondary mains in series, and the 50 volt lamps on 100 volt converters by putting the primaries in series; in fact, it is possible to obtain almost any combination with converters, which is in itself a very great convenience.

Mr. Leonard was "impressed" by our carrying a spare armature for our five large dynamos. We do. We also carry a spare armature for each size of our direct current machines, and several spare armatures for our arc machines. We also carry spare connecting rods for our engines, spare straps, brasses, keys, piston rings, etc., and spare tubes for our boilers; and so, I think, should every superintendent who has 15,000 lights on his conscience.

It strikes Mr. Leonard as being rather odd, that in the "home of the alternating system" we should find it necessary to establish two stations. Our company established, not two, but four stations, and why? Because with no practical continuous system could we operate our lights at the distance required. The first effect of the introduction of the alternating system was to completely wipe out one of these stations, of 1,800 lamps of 16 c. p. each, and to operate the whole from our central station. Will Mr. Leonard tell us how he would do this with the three-wire system, the distance between the station and centre of distribu-

tion in the building being 3,000 feet, and all the lamps burning at once, 12 hours per night? The second effect of the introduction of our alternating system is the stopping during part of the time of a second station of 1,500 lights average load, with the near prospect of its permanent shut down, and the removal of the machinery to our general station, the distance in this case being 13,000 feet from station to station. Will Mr. Leonard tell us how he could run this on the three-wire system?

The only reason that we do not contemplate the shut down of the third station is that "Station A," where we have established our business office, is in the centre of the city, and we cannot get room enough to put in the necessary power. We shall accordingly use "Station B" simply as a generating station, one mile from the heart of the city, and shall bring over from that station the necessary current for 10,000 16 c. p. lamps, distributing it from our central station, "Station A." Will Mr. Leonard tell us how he would tackle this case?

Mr. Leonard quotes very extensively from English electricians. I am a "Blarsted Britisher" myself, and do not hesitate therefore to remind Mr. Leonard what he surely heard Professor Forbes say at the Pittsburgh convention, that "In England they know very little about the alternating current system as compared to what is known here in America."

With regard to the danger of a connection between the primary and the secondary, does Mr. Leonard mean to say that a revolving armature with two windings on it side by side, which his description would seem to imply, is safer than the two stationary coils entirely separated from one another and from the iron core and case by mica, insulating tape and air space, which constitute the alternating converter?

Mr. Leonard says "I do not consider that the lamps, as they existed in that station at those long distances, were any more liable to be continuous than in the case of a series system, which of course can be operated at the same distance, and probably with equal results." The lamps, as they existed, were simply run from the second station, which has its dynamos shut down, and its bus wires, by the closing of a double pole switch, charged with current from our main station. Will Mr. Leonard tell us of a series system in which the individual lights can be cut off at the sweet will of the customers, with a corresponding decrease in current from the station?

I do not intend to enter into the question of the first cost of converters, as against the cost of copper, etc., with Mr. Leonard. By the use of the alternating system we are enabled to rent lights at a distance from our station of from two to three miles. As a consequence, without a single attempt at canvassing, we have increased our lights in eight months from 4,000 to 15,000 lights of 16 c. p. each; in one case, 1,800 lights in one building, 3,000 feet from the station; in another case, 1,200 lights 2,000 feet from the station; in another case, 800 lights 2,400 feet from the station; and on the same feeder, 300 at 12,000 feet from the station—all with less than 6 per cent. loss under full load from switch-board to lamp. Add to this that we can operate all of these from our "Station B," 5,000 feet further away, with only 5 per cent. additional loss. When Mr. Leonard has shown a case where a station operating the three-wire system has taken such contracts, *and stand ready to take them at any minute*, I shall be glad to discuss the commercial side of the matter with him.

I have not asked Mr. Leonard to answer any questions based on "average distribution over a radius of x feet" (all of which planning is very pretty on a map, but very little average distribution has ever come my way), but have placed before him certain cold blooded every-day problems which we have solved, without any trouble, by means of the alternating system.

I am sorry to have taken up so much of your space, but as superintendent of this company, I do not care to have it appear that after having used the direct current system, I should recommend any system which is not as practicable and economical.

T. CARPENTER SMITH,
Superintendent, The Allegheny County Light Co.

Pittsburgh, Pa., March 15, 1888.

THE COUNTER ELECTROMOTIVE FORCE OF TRANSFORMERS, OR CONVERTERS.

THE law formulated by Lenz, and its converse, as aptly put by S. P. Thompson, are that an induced current is always such that by virtue of its electro-magnetic effect it tends to stop the motion that generated it, and that the motion produced is always such that by virtue of the magneto-electric inductions which it sets up, it tends to stop the current.

Now, in a certain sense, a converter or transformer may be regarded as a stationary dynamo; only it is the *current* which is moved or alternated in polarity instead of the armature being moved mechanically. A corollary may therefore be deduced, which is that the induced current tends to stop the inducing current. That this tendency exists is not doubted, but perhaps we are hardly yet, all of us, beginning to realize to what an extent the phenomenon does actually occur. It seems at first sight scarcely credible that with a pressure of 1,000 volts at the terminals of the primary coil of a converter and only a few ohms of actual resistance in the coil, the current passing is reduced by self-induction to a small fraction of an ampere. One is so accustomed to the invariable application of Ohm's law that it is easy to forget the possibility of its being superseded or modified by another law, as it is in this case. If Ohm's law alone applied, such a volume of current would pass as would instantly fuse the whole apparatus.

We are referring, it will be understood in our present remarks, to an alternate current converter adapted for use in a constant potential circuit, the only one now used in practice. When these converters are connected in multiple, as is invariably the case, assuming them to be properly constructed, of course, we have a most beautiful system—a multiple system with a metallically closed circuit of perhaps less than an ohm's resistance, a pressure of, say, 1,000 volts, and yet no current passes! i.e. *practically* none.

So far we have assumed that no secondary circuit exists, and that the primaries alone are in operation. Here we should say that Ohm's law *does* in a certain sense apply; with 1,000 volts pressure, a closed circuit and no current there *must* be some resistance, and that *infinite*. This is, in fact, the case, but the "resistance" is not such as we have been used to call by that name. The counter-electromotive force of self-induction offers what is equivalent to resistance to the passage of the current, and with open secondaries this virtual resistance *is* practically infinite. Now, let us see what causes this, and in what manner it is modified by the action of the secondary coil. The primary conductor is of course, coiled upon a core of iron, and the current magnetizes this core. The magnetism thus produced reacts, and assists in inducing the current which tends to stop or stem back the impressed primary current. Self-induction would exist without iron, but the presence of iron enormously intensifies the action.

Let now the secondary circuit be closed through some resistance. What follows? A current will be induced in this secondary conductor of a volume, other things being equal, dependent upon the resistance of the secondary circuit, and this current will be in the opposite direction to that of the primary. It will therefore operate to *pro tanto* demagnetize the core. The counter E. M. F. or virtual resistance is thereby reduced, and more current allowed to flow in the primary. As an example, assume a transformer with a ratio of conversion of 20 : 1 — 1,000 : 50. The secondary being closed through, say 50 ohms, at 50 volts, 1 ampere will pass in the secondary, and 1-20 of an ampere in the primary. It will, therefore, be seen that there is then a counter effect in the primary which is equivalent to a resistance of 20,000 ohms. As the resistance of the secondary is decreased by introducing more lamps into circuit, and thereby increasing its current, its neutralizing effect also increases, until with 20 amperes in the secondary there will be 1 ampere in the primary, and a counter E. M. F., or virtual resistance of 1,000 ohms. There is thus an automatic sliding scale, the variations of counter E. M. F. in the primary following the variations in the secondary in a beautiful proportion. It is a pertinent question to enquire what would be the result of reducing the resistance of the secondary circuit to *nil*. It would be that an infinite current would flow in both the secondary and primary coils, the engine would be pulled up or *something would have to go*, and in practice it is this last which occurs, and therefore a fusible cut off is used as the thing which it is best to *let go*. Thus, when an accidental short-circuit occurs in the lamp circuit, the excess of current instantly melts the fuse in the secondary, or primary, or both, and the line is opened, no evil effect following save the extinction of the lamps.

In the above short sketch of one phase of the action of converters, we have not ventured into the labyrinth of scientific lore on co-efficients of self and mutual induction, waves of E. M. F. and current, *hysteresis* and the like, but have simply regarded the matter from a practical point of view.—*Modern Light and Heat.*

ELECTRICAL TRACTION.

IN the last two or three years a number of street car lines have been equipped with electric motors, and most of them have been successful in spite of the inexperience of those who have done the work,—an inexperience due to the newness of the field. The number of electric railroads under way is increasing rapidly, and for certain classes of work the motor seems destined to take the place of the expensive and overworked car horse.

As yet the greater part of the lines equipped have been for city tramways, generally in the suburbs, where there is comparatively little street traffic. This, however, is only a beginning, more useful in the experience it gives, and in the problems that are brought up and solved, than in the absolute results: for the question of the application of electricity to traction is a very broad one, and does not stop at street railways. The elevated railroads may be run by electric motors; already motor cars are

used in mines, where there is an extended field for their use; and it is possible that a few years will displace the steam locomotive, and substitute in its place powerful electrical locomotives.

There is no apparatus for the transformation of energy that compares in simplicity and efficiency with the dynamo-electric machine and electric motor. The steam engine transforms perhaps 15 per cent. of the energy of coal into mechanical work; while the efficiency of a good dynamo may be 92 per cent., and a motor may have as high an efficiency. If, therefore, we transform mechanical work into electrical energy by a dynamo, and retransform it to mechanical work again by a motor, we have a total loss of perhaps 15 per cent. It may be easily shown that in many cases it would be profitable, by taking advantage of the higher efficiency of large power plants, and the comparatively small cost of attendance, repairs, etc., per horse-power, to generate all the mechanical energy needed in a district at some central station, and distribute it by dynamos and motors to the consumers, displacing the small steam or gas engine plants previously used.

For traction work the problem is not to replace stationary steam engines or gas engines, but to replace horses, cables and locomotives. This problem is being attacked, and will doubtless be at least partially solved.

Before taking up the relative merit and costs of different systems, let us consider the broad questions that are involved. The questions are: (1) How can we best produce the electrical energy needed? (2) How can we best get it to our motors? and (3) After we get it there, what is the best way to apply it to traction?

Under the first head there are a good many things to consider, and many of these can only be answered by knowing the exact conditions of our installation. We can say generally that for a given horse-power needed at our motor we should so choose our source of power and location of generating station that the interest on first cost of plant and conductors (supposing we use them), the total depreciation, and the cost of the power *generated*, should be a minimum.

We will discuss these questions more fully when we come to the question of cost. To show the nature of the problem that might arise, suppose we have a railroad line from Philadelphia to New York to be run by electric motors. We would possibly find it best to have a number of generating stations along the line, at distances apart of, say, 20 miles. Now, if there were no natural sources of power near the tracks, we would have to calculate the best distances apart for these stations, knowing the cost for a horse-power with plants of different sizes, the cost of copper for conductors, the cost of a ton of coal at different points on the line, etc. The problem would not be a difficult one. If, however, there was at some distance from the line a source of natural power,—a waterfall, for example,—we would have to redistribute our stations, and calculate whether it would cost less or more to utilize the waterfall, decreasing the cost of power, in that we do not have to pay for coal, but increasing the size of plant for a given electrical energy at the line (for we must supply the needed energy *plus* the loss on our lines), and increasing the outlay in conductors. Of course, this is all a very definite question, presenting little difficulty to the electrical economist. When we consider that some railroad lines have distributed near them water-power capable of running all of their trains, with help at long intervals from steam generating stations (even windmills are not to be despised in some cases), and, when we further consider that the conditions are much simpler than in city traffic (we can use high potentials and unsightly devices if we choose), it encourages one to predict a future for electric railroads.

If, as we have so far assumed, we are going to transmit the electrical energy to the motors by conductors, it is evident that the potential we can use comes in as a factor. In cities we are usually limited to a comparatively low potential,—a maximum, say, of 500 volts. This has the effect of locating our generating station as near the line as possible,—in the middle of the line if we can get it there,—for the cost of conductors would be great if the station were too far from the line.—*Science.*

THE TELEPHONE DECISION IN BRIEF.

EXTRACTS FROM THE OPINION DELIVERED BY THE SUPREME COURT MARCH 19, AND PRINTED IN FULL IN THE SUPPLEMENT OF THE ELECTRICAL ENGINEER, MARCH 22.

THE ART.

THE question is not whether vocal sounds and articulate speech are used synonomously as scientific terms, but whether articulate speech is one of the vocal or other sounds referred to in this claim of the patent.

Electricity left to itself will not do what is wanted. The art consists in so controlling the force as to make it accomplish the purpose.

How to do it was the question. Bell discovered that it could be done by gradually changing the intensity of a continuous electrical current so as to make it correspond exactly to the changes in the density of the air caused by the voice.

This was his art.

He then devised a way in which these changes of intensity could be made and speech actually transmitted.

Thus his art was put in a condition for practical use.

The law does not require that a discoverer or inventor, in order to get a patent for a process, must have succeeded in bringing the art to the highest degree of perfection. It is enough if he describes the method with sufficient clearness and precision to enable those skilled in the matter to understand exactly what the process is, and if he points out some practicable way of putting it in operation.

This Bell did,

REIS.

It is not contended that Reis ever succeeded in practically transmitting speech, but only that his instrument was capable of it, if he had known how.

He did not know how.

All his experiments in that direction were failures.

With the help of Bell's later discoveries we now know why he failed.

We have not had our attention called to a single item of evidence which tends in any way to show that Reis, or any one who wrote about him, had in his mind anything else than that the intermittent current, caused by the opening and closing of the circuit, could be used to do what was wanted. No one seems to have thought that that there could be any other way.

It was left to Bell to discover that the failure was due, not to workmanship, but to the principle which was adopted as the basis of what was to be done

The true way was to operate on an unbroken current, by increasing and diminishing its intensity.

Such was his discovery, and it was new. Reis never thought of it, and he failed. Bell did, and he succeeded.

To follow Reis is to fail; but to follow Bell is to succeed.

The difference between the two is just the difference between failure and success.

Dr. Van der Weyde copied Reis, and it was not till after Bell's success that he found out how to use a Reis instrument so as to make it transmit speech. Bell taught him what to do to accomplish that purpose.

MCDONOUGH.

We presume it will not be claimed that he is entitled to more than he asked for, * * * a circuit breaker so adjusted as to break the connection by the vibration of the membrane. The patent office was clearly right in holding him to have been anticipated by Reis.

DRAWBAUGH.

Marx,—Klemm,—Levy,—Wolf.— * * On the 6th of March, 1880, these parties entered into an agreement.

On the 21st of July, 1880, Drawbaugh, claiming to have invented new and useful improvements in the transmission of vocal speech, * * assigned to Klemm, Marx, Wolf and Levy, the full and exclusive right to the said inventions.

On the morning of July 22, 1880, the following article appeared in the *Cincinnati Commercial*:—

"An application for a patent was filed to-day, that in consequence of its vastness of interest, as well as the wealth of prospect, renders it a subject of national interest. * * The cash capital of the company is $5,000,000 * * and in about 60 days will open up the telephone, which will certainly result in the driving out of all telephones in the market, save the ones they hold, or else in compelling the Gray, Bell and Edison lines to pay the new company a munificent royalty. * * It appears that the inventor of the telephone is a poor mechanic * * named Daniel Drawbaugh. * * A large number of capitalists * * assert * * that it will not be long till they have entire charge of the telephones, not only in this country but in the world, and that they will be able to establish lines by which messages can be transmitted for almost a song."

On the 30th of August, 1880, the People's Telephone Company was incorporated. On the 4th of September, 1880, Klemm, Levy, Marx and Wolf, in consideration of $4,999,550, represented by 99,991 shares of stock, assigned and transferred to that company all their interests.

At this time and in this way, the attention of the general public was called for the first time to the fact that Drawbaugh claimed to have anticipated Bell in the discovery of the telephone. Bell's success had been proclaimed more than four years before at the Centennial Exhibition in Philadelphia. Gray, Edison, Dolbear and others had either claimed for themselves, or others had claimed for them, priority of invention and discovery, and Bell had thus far been sustained as against them all. Blake had perfected his microphone apparatus, and Bell's patent had become a great commercial success.

The People's company either began, or threatened to begin operations, and on the 20th of October, 1880, the Bell company brought suit against it.

The bill * * avers that Klemm, Marx, Levy and Wolf, having heard that Daniel Drawbaugh * * had made some experiments relating to * * telephones * * entered into an

arrangement with him to set up and claim that he was the first inventor.

If Drawbaugh had ever made his pretended inventions * * "knowledge thereof has been withheld * * except so far as they have been disclosed within the three months last past by certain newspaper publications."

The People's company began taking depositions on the 19th of April, 1881, but Drawbaugh himself did not appear as a witness until December 7th, 1881.

All that any of the witnesses could say * * was that they had used one or more of the different instruments, and heard sounds and sometimes words * * and that Drawbaugh told them the sound was carried on the wire by electricity.

There was nothing whatever produced in print or in writing on the subject, nor even a memorandum or drawing of any kind, and there is nothing in the testimony to show that Drawbaugh ever told any one how his earlier instruments were made, or what his process was, until he was called as a witness in December, 1881. * * This was nearly 20 years * * after he had begun his experiment, nearly seven years after he had made and used * * perfectly constructed and finished instruments. It was also nearly six years after the date of Bell's patent, more than five years after the success of his discovery had been proclaimed at the Centennial Exhibition, * * four years after it had become an established success.

Under these circumstances it becomes important to consider the conduct of Drawbaugh in reference to his alleged invention during his 20 years of eventful history. * * If his present claim is true, he had in his shop * * telephones that were substantially perfect, months before Bell got the clue to his subsequent discovery.

The Centennial Exhibition was opened in May, 1876. Drawbaugh visited it on the 17th of October, 1876, remaining four or five days.

If what he claims now is true, he had then in his shop * * good instruments * * capable of transmitting speech, and some of them but just finished. * * Bell's apparatus had attracted marked attention. The matter was much discussed in the public press, yet it never seems to have occurred to Drawbaugh to take any of his telephones with him when he went, although they were small in size and some or all of them could have been carried without serious inconvenience.

He spoke to no one about what he had done himself. He made no special effort to find out whether that which was on exhibition was in any respect like what he had at home, neither did he, when he got home, * * * say anything to his neighbors or visiting friends about what he had seen or heard. He had apparently lost all interest in talking machines.

Not so, however, with his other inventions. * * During the early part of 1876, he was much interested in building an electric clock, which he thought of exhibiting at the Centennial.

On the 20th of September, 1878, he applied for a patent for improvements in batteries for electrical clocks.

On the 14th of January, 1879, he filed in the patent office an application for an improvement in rotary measuring faucets.

On the 2d of July, 1879, Drawbaugh filed another application for an improvement in water motors.

It is impossible to believe if Drawbaugh had in his shop when he reached home from the Centennial, exhibits D, E, L, M, G, O and H, or even D and E alone that he would have set himself at work in the first instance in developing the clock enterprise, or perfecting his former conception of the measuring faucet, instead of calling attention to his great discovery of the telephone * * which he could not but have known was even then attracting the greatest attention. * * No man of his intelligence * * * could remain silent under such circumstances.

It is not even pretended that he took any of these instruments outside of his own village until May, 1878.

Bell's success was proclaimed in the *Harrisburg Patriot* as early as February 26, 1877. * * If Drawbaugh had at that time in his shop the machines it is now claimed were there, complete as they now are, in August 1876, * * there cannot be a doubt that he would have taken them to some place where they could be tried, and show that they would do what he had all along claimed for them. * * It would certainly have been easier then * * to show that he antedated Bell, than it was three years afterwards, when he was brought into the controversy through the instrumentality of his associates, not, as must be evident to all, to get a patent for himself, but to defeat that of Bell.

From the time of his visit to the Centennial until he was put forward by the promoters of the People's company, nearly four years afterwards, to contest the claim of Bell, he was silent, * * while if he had really done what these witnesses say he did, he would certainly have spoken. There is hardly a single act of his * * * that is not entirely inconsistent with the idea of a complete discovery or invention by himself which could be put to any practical use.

But there is another fact * * equally striking * * F, D, C and I, were in no condition for use when produced and put in evidence. They were mere remains. No one but Drawbaugh could state how they were made or how they were to be used. He undertook to reproduce some of them. * * The Bell company proposed that they should be tried to see if they would do what the witnesses said had been done with the originals. * * * The proposition of the Bell company was accepted, and the reproductions tried in March, 1882, under the most favorable circumstances. It was substantially conceded that the trial was a failure.

To our minds the result conclusively shows that the original instruments could not have been of a construction similar to the reproductions, and that what they had done was produced by other means.

To hold that he discovered the art before Bell did would be to construe testimony without regard to the ordinary laws that govern human conduct.

NEW YORK AND VICINITY.

Underground Wire Enterprises Stimulated by the Collapse of Communication during the Blizzard, March 12 and 13.—The Board of Electrical Control.—Another Rapid Transit Scheme.—Electric Traction on the Fourth Avenue Line.—Trial of a Storage-Battery Car in Jersey City.—Electricity Proposed for Atlantic City Railways.—Impure Air from Pneumatic Tubes in a District Telegraph Office.—The Sheriff Enjoined from Selling Property of Several Telegraph Companies which have not Paid their Subway Assessments.—A Seaboard Cable Scheme to Head off Blizzards.

DURING the past month subterranean enterprises of all characters experienced a decided stimulus, for nearly every system of intercommunication above ground was paralyzed completely for 24 hours by the blizzard of March 12th and 13th. The process of recuperation has been slow, especially with telegraph and telephone circuits, for broken poles are not readily replaced. It appears almost certain that a serious outlay must be incurred, probably once in five years on an average, in repairing damages caused by either snow or sleet storms. If the electric light lines had suffered in an equal ratio no doubt considerable opposition to the underground scheme would be removed. As it is, the lighting companies will be very glad to see all of their neighbors' wires buried provided they are not disturbed.

The legal status of the board of electrical control is being gradually determined by the various decisions promulgated. Attorney-General Tabor has given his opinion that the board in this city is a state and not a municipal body. Mayor Hewitt may be considered responsible for raising this question, he having undertaken to bring the appointments by the board under jurisdiction of the municipal civil service rules. Another rapid transit scheme has made its appearance since the snow blockade, but was probably very fully matured before that event. The plan is a very comprehensive one, involving the purchase of a right of way on the west side, and the construction of a railway under the streets and blocks, and operated by electricity. Fireproof warehouses are to be erected on the land purchased by the company, and a necessarily large sum of money will be required to complete the work. As the amount of $1,250 has already been expended in payment of the state fee for organization, it is probable that the incorporators mean business.

The New York and Harlem Railroad Company, operating the Fourth Avenue horse railway in this city has made a formal applicationto the common council of the city for permission to substitute electric for horse power on its lines. It is generally known that a car has been run over this route for some little time past, with considerable regularity, operated by the Julien storage battery. There appears to be little doubt that the requisite license will be given, yet a public hearing will be granted on April 6th, to all who are interested either for or againt the project.

A trial trip of the storage battery car on the Jersey City and Bergen Railroad Company was not altogether satisfactory. It left the ferry with a number of passengers, but while on Grand street (Jersey City) there was a breakdown, and a consequent loss of some time before the car was able to proceed. As soon as these petty annoyances are overcome the company proposes to introduce electric propulsion generally on its lines.

The Pennsylvania Railroad Company is also said to be contemplating the substitution of electricity for horses on the Atlantic City railways.

One of the accompanying evils of a dense population is the occupation of unhealthy locations by human beings. Even the ordinarily impure atmosphere of a basement may be made worse by artificial means, and this complaint is made regarding the quarters occupied by the American District messengers at the Twenty-third street and Fifth avenue office. The pneumatic tubes from down-town open into the apartments, and the accumulation of sewer and illuminating gas driven through them is at times almost overpowering. Under the most advantageous circumstances a crowd of city messengers should be subjected to occasional fumigation, but a supply of fresh rather than foul air would tend to greatly lessen the evil effects of overcrowding.

Judge O'Brien of the Supreme Court has granted a preliminary injunction restraining sheriff Grant from selling the property of the Postal Telegraph Cable, the United Lines and the Commercial Telegram companies because they have not paid the assessments made upon them to cover the expenses of the subway commission. The state comptroller issued a warrant to sheriff Grant to collect the various assessments which, in the case of the Postal company amounted to $726, but it was not paid. the counsel of the company and its two associates having decided that it was levied in violation of the state constitution. There are several allegations made why the tax should not be paid. The comptroller had apportioned $50,000 for New York and $30,000 for Brooklyn. These amounts the companies consider unreasonable, claiming that $15,000 for this city and $9,000 for Brooklyn would be sufficient. It is also alleged that the assessment was made by the comptroller without having received a detailed statement of the expenses incurred by the board.

Some genius has proposed a system of submarine cables connecting the various important cities along the seaboard, so that electrical communication could be maintained in spite of blizzards. The practical utility of such a scheme would be doubtful during such a snow storm as prevailed on the 12th, for the reason that there was nothing which could be effectively done upon the receipt of telegrams. Business was practically suspended. First provide against the blockading of transportation lines, or, if considered expedient, establish subterranean lines giving an opportunity for communication with inland towns. An underground wire along each railroad line by which instructions and authority could have been given to agents and conductors, would have greatly facilitated the movements of trains during the late embargo.

NEW YORK, March 22, 1888.

PHILADELPHIA.

The Edison Electric Light Co. of Philadelphia; The First of Their Series of Stations.—The Suit of the City against the Baltimore and Ohio Telegraph Co.—The Philadelphia Electrical Society.—The Post Office Building Lighted by the United States Electric Light Co.—Retirement of Mr. H. Bentley from the Presidency of the Bell Telephone Co., of Philadelphia.—Mr. James Murray succeeds him.—Mr. W. B. Gill succeeds Mr. Murray in the Vice-Presidency.

THE Edison Electric Light Co. is about erecting the first of a number of electric light stations, which in a short time will supply both light and power to the entire city. The directors of the company are: Thomas M. Thompson, B. K. Jamison, Samuel B. Huey, Charles M. Swain, John Lucas, H. Blake Tyler, Edward H. Johnson, D. M. Lindsay and Amos R. Little. The company intends to furnish both light and power in large and small quantities. Sixteen candle power will be the standard size of lamp ordinarily used.

To understand the enormous scale on which the Edison Co. proposes to carry out its plans, a description of its first building somewhat in detail, will be necessary.

Its principal architectural feature is its great strength. The materials used are brick, stone and iron, the iron beams being of great size and weight, supported by heavy columns and pillars. This kind of construction is made necessary by the interior arrangement of the plant. The building will have a front of 70 feet on Sansom street, and will extend 100 feet back toward Walnut street. Its cornice will rise 114 feet above the pavement, overshadowing all the roofs in the neighborhood.

Twenty engines, of 250 h. p. each, will be placed on the first floor. Forty dynamos, with a capacity of 1,500 lights each, or a total capacity of 60,000 lights, will rest on the second floor. On the floor above the dynamos will be the workshops where wires and conduits are prepared for laying in the streets and making connections with houses. On the fourth floor huge boilers, with a capacity of 5,000 h. p., will be placed. In the fifth floor will be stored over 1,000 tons of coal at a time. The sixth floor, where light and air will abound, as its windows will look 20 feet above the roof of the Continental Hotel, will contain the general offices of the company and space for its clerical force.

This sounds like an amazing way of erecting a plant, with huge boilers and tons of coal in the air, but this reversal of the ordinary arrangement of machinery is due to the necessity of concentrating enormous power within a limited space. It also necessitates construction of the most massive kind, in the first place, the whole lot will be covered with a deep bed of concrete, four feet in vertical thickness. Resting on this bed will be the foundation walls, five feet thick. The 20 engines on the first floor, which will each hum at the rate of 200 revolutions a minute, are of the high-speed Armington and Sims type. They will each be firmly planted on a concrete monolith, 15 feet square. These 20 monoliths will rest upon a bed of sand one foot thick, which in turn rests upon the bed of concrete four feet thick. The dynamos on the floor above the engines will weigh seven tons each, and will make 650 revolutions a minute. They will rest on heavy iron beams supported by iron pillars, each pillar being capable of upholding 500 tons. Other pillars and beams support the floors above the boilers, furnaces and coal. The coal is to be driven upon scales, weighed and dropped into a pit. Chutes will be so arranged that the coal can be readily loaded on elevators and carried to the fifth floor. There the coal will be dropped into bins, from which a pipe runs at an inclination to the furnace of each boiler. All this machinery for delivering and feeding the fuel under the boilers will be strongly but simply designed to save time and handling.

On the third floor there will be placed two blast fans, capable of driving 50,000 cubic feet of air per minute into the furnaces. The smoke and other products of combustion will be carried from the furnaces into two chimneys of nine feet internal diameter. These chimneys, or smoke stacks, make an original detail of the building, for they will appear merely as bay windows, start-

ing at the third floor and reaching to the roof. These apparent bay windows will be at the rear of the building; the bay windows will contain spiral staircases. There will also be a passenger elevator in the front portion of the structure.

Pipes will carry the steam from the boilers to the engines on the first floor, and a huge exhaust pipe will rise from the engines to the top of the building. This exhaust pipe will be four feet in diameter at its top, and probably there is no exhaust pipe in use in Philadelphia as large as this.

Scientific appliances will be used to regulate the distribution of electricity and to secure perfect uniformity and regularity in the brilliancy of the lamps. Mr. Edison's inventions will be utilized in every possible way. There will be 35 great feeding mains running from the station. Each feeding main consists of three large bars of copper. To each of these mains a regulating apparatus is specially attached, so that the pressure is constantly kept at exactly the same point, whether one lamp or 1,000 may be burning on a main. In other words, this regulating apparatus keeps the quantity of current supplied to a main exactly proportioned to the demand.

When this great station on Sansom street is completed it will have cost the company about $1,000,000. This plant is only the beginning of the plans of the company. It will supply only the central portion of the city, and it is expected that other stations nearly, if not quite, as large, will be erected in Kensington, Richmond, Spring Garden, Northern Liberties, Germantown, Southwark, West Philadelphia and elsewhere. Already the company has expended $250,000 in copper conductors, 11 miles of which are laid under Chestnut and Walnut streets, between Twentieth and Fourth streets. During the coming summer 20 miles more of conductors are to be laid, extending between the Delaware and the Schuylkill, under Market street, from the Delaware to the Public Buildings, and on intersecting streets connecting with Spruce, Pine and South streets.

City solicitor Warwick held a conference recently with his assistants in regard to the case of the city against the Baltimore and Ohio Telegraph Co., to recover $50,000 for the alleged breach of the constitution in selling out to the Western Union Telegraph Co. Mr. Warwick declined to tell the result of the conference, however.

Councilman John H. Fow, who has been very active in the agitation of the matter since the alleged consolidation of the two companies, said that Mr. Warwick has two remedies: one would be to rule the defendant into court to show cause why judgment should not be entered for want of a sufficient affidavit of defense, and the other would be to rule them to plead and try the matter before a jury. Mr. Fow said that he was convinced that the city would recover the $50,000.

Nearly 500 persons gathered in the cozy rooms of the Philadelphia Electrical Society at Nos. 1712 and 1714 Chestnut street, a few nights since. It was the society's first reception. There was an interesting programme of vocal and instrumental music and recitations. An address of welcome was delivered by first vice-president John C. Sager. After the concert the spacious room was cleared and the members and their friends enjoyed a series of dances, with an intermission for refreshment. The society is composed of gentlemen engaged in electrical pursuits in this city. Though it is less than a year old it has nearly 200 members. The president is M. D. Law, of the Brush company; vice-presidents, John C. Sager, of the City Electrical Bureau, C. W. Knapp and H. B. Cutter, of the Pinkham company; recording secretary, G. C. Brooks, of the Adams' Express Co.; financial secretary, H. J. Curl, of the Baltimore and Ohio District Telegraph; treasurer, A. F. Reed, of the Baltimore and Ohio Telegraph Co.; board of managers, F. W. Griffin, American Telephone Co.; William McDevitt, Insurance Patrol; D. A. Curl, Baltimore and Ohio District Telegraph; R. J. Park, Pennsylvania Railroad; A. H. Manwarren, Brush company; A. W. Ford, Western Union; F. A. Lee, Philadelphia Local company; C. L. Chapin, City Bureau of Water.

The post office building has been supplied with a new electric light plant. There are seven dynamos in the cellar, driven by two engines of 150 h. p. each. They supply 3,000 lights of 16 c. p. each. The work has been done under the directions of superintendent E. M. Walsh, and has been going on for the past six months. The lighting is highly commended. The work was done by the United States Electric Co.

Henry Bentley has resigned the presidency of the Bell Telephone Co., of Philadelphia, and has been succeeded by James Murray, who was vice-president of the company. Wm. B. Gill, superintendent of the Western Union Telegraph Co., takes Mr. Murray's place as vice-president.

PHILADELPHIA, March 13, 1888.

BOSTON.

Public Electric Lighting in Boston.—Underground Conduit Schemes. Extension of the Police Signal System.—General Tearing up of Boston Streets.—The Output of the Bell Telephone Co.—The Boston Electric Club.—A Mysterious Fire.

ON September 27, 1886, the following order was passed by the board of aldermen:

Ordered, That the superintendent of lamps be and be hereby is authorized to contract with any responsible electric lighting company or companies, for furnishing the city with electric lights for public street lighting, for a period of not exceeding three years from the date of contract; the expense thereof to be charged to the appropriation for the lamp department;

and, under the authority of and according to the provisions of this order, contracts have been made with the Brush Electric Lighting Co., of Boston, the Citizens' Electric Light Co., the Merchants' Electric Light and Power Co., and the Charlestown Gas Co., for a period of three years from the date of said contract, viz., January 7, 1887.

The following is a copy of the contract as made with those companies:

This agreement, made this day of , A.D. 1887, by and between the Electric Lighting Co., a corporation established by law, having a usual place of business in Boston, Massachusetts, of the first part, and the city of Boston, of the second part:

Witnesseth:

That the said Electric Lighting Co. agrees to furnish electric lights, of not less than 2,000 c. p. each, according to the French standard of measurement, and to the satisfaction and acceptance of the superintendent of lamps of said city, in such number, and such places in the streets, lanes, parks, or other public places in said city, as the board of aldermen of said city shall from time to time direct, and keep the same lighted to the satisfaction of said superintendent, from sunset to sunrise of each and every night during the continuance of this contract, or during such hours of the night as the said superintendent of lamps may direct.

And said company further agrees to indemnify and save harmless said city of Boston from and against all claims and demands for damages, costs, expenses, or compensation for or on account of the erection, maintenance, or use of any of said lights, or of the wires or apparatus connected therewith; and also against any and all claims by reason of any infringement of any patent right in the use of said lights, or the apparatus or machinery connected therewith.

The said city of Boston agrees to pay for said lights, furnished and lighted as aforesaid, to the satisfaction of said superintendent, at the rate of 65 cents per light for each and every whole night the same are lighted; and at the same rate per hour of lighting, where, by order of said superintendent of lamps, such lights are lighted for a portion of the night only, and to make payment thereof monthly.

It is also understood and agreed that, in case of the failure or neglect of said company to furnish and keep lighted said lights, or any of them, as above agreed, there shall be forfeited and deducted from the sums to be paid by the city of Boston under this contract, an amount for each lamp or light so omitted to be lighted, equal to double the rate to be paid for lighting the same under this contract, as above provided.

This contract shall be and continue in force for three years from and after the day of , 1887.

It is also understood and agreed that, in case of any alteration of this contract, so much thereof as is not necessarily affected by the change, shall remain in force upon all the parties hereto, and no payment for any work done under any alteration shall be made until the completion of the whole contract; and the adjustment and payment of the bill then rendered for such work shall release and discharge the city from any and all claims or liability on account of any work performed under this contract, or any alteration thereof.

According to the municipal reports there were in use for public lighting:

	Arc Lights.
January 1, 1883	114
January 1, 1884	381
January 1, 1885	401
January 1, 1886	446
January 1, 1887	501
December 15, 1887	577

These lights are furnished by the following named companies:

Brush Co.	318
Weston Illuminating Co.	136
Charlestown Gas Co.	51
Merchants' Co.	27
Citizens' Co.	45
Total	577

The rate paid by the city is 65 cents per night, and the lights are used 365 nights per year.

On the 1st inst., Charles Babbidge and others appeared before the aldermanic committee on electric wires in advocacy of a petition to lay a conduit for running wires underground. J. M. Olmstead stated that the system for which the right was asked was what was known as the "solid" system, and made the offer to supply all the wires necessary for use by the city free of cost, which was more than any other system had offered to do. Henry C. Spalding, the inventor, said that by this way all wires were buried together in a mass, and that telegraph and telephone wires could be run in the same conduit. By his system there was a saving of space, and there was no necessity of tearing up the streets to any great extent. The committee took the matter under consideration.

On the 21st, police commissioners Whiting and Osborne were before the legislative committee on cities to ask that the amount that the board is allowed to take the coming year from the receipts of liquor licenses for the purpose of extending the police-signal system be increased from $75,000 to $150,000. The commissioners believed that the additional amount asked for would place the system in all the stations in the city, and that the most of it would come from the increase in license fees. They stated that some opposition to the system was manifest at the city hall, and for that reason the Legislature was asked to act. Mr. E. B. Welsh charged that the commissioners were using too much money, and that they did not need $150,000 when a system could

be put in for $100,000. Upon questioning it was brought out that Mr. Welsh had a rival system to those in use, and it was decided that the system to be adopted lay in the discretion of the commissioners.

City solicitor Bailey said that if the Legislature increased the city's burdens it should raise the tax limit; and the hearing was then closed.

With the conduit, hot water and cable road enterprises the streets of Boston are likely to be torn up for several years to come. The West End Railroad have applied for permission to put in cable roads; experiments were made last fall and early winter with the several motors operated by accumulater batteries; and President Whitney said before the board of aldermen that "The electric railway as yet had not been proven perfectly practical in all kinds of weather;" but that they were still experimenting with the matter.

The statement of the output of telephones by the American Bell company for the month ended Feb. 20, compares as follows with the statement for the same month of last year:

February—	1888.	1887.	Increase.
Gross output	3,972	3,405	567
Instruments returned	2,088	1,918	170
Net output	1,884	1,487	397
Dec. 21st to Feb. 20th—			
Gross output	8,002	7,379	623
Instruments returned	3,760	3,874	*114
Net output	4,242	3,505	737

* Decrease.

The Boston Electric Club has evidently come to stay, and is striking its roots deep into the ground; many who were indifferent or doubtful of the expediency of the use and utility of such an institution, are falling into line gracefully. On the evening of the 6th, Mr. George S. Page spoke before the club, upon "Combinations of Gas and Electric Lighting," to an applauding and appreciative audience.

The "great storm" of the 12th did not affect eastern New England as it did New York and the region round about; the telephone service has been good in Boston; some of the suburban lines are down, but, generally speaking, the loss of all kinds has not been anything comparatively. The long-distance copper line worked well to within a few miles of New York city; our local papers have been furnished news by the long-distance lines to the several points in New England, the telegraph lines being down. Hereafter it will not be in good form to refer to "cold and bleak New England."

The electric light in one of our fine business buildings, the "Simmons building," was on a rampage on the night of the 12th. Fire was seen to come from the recording resistance boxes inside the building, and it was discovered that the cut-out on the outside of the building was placed so high that no one could reach it. The pressure on the main line was supposed to be 500 volts, the current being furnished from a central station, and the boxes were supposed to be protected by safety fuses. The cause of the fire is obscure, and excites much interest in electric light circles.

BOSTON, Mass., March 16, 1888.

CHICAGO.

The Chicago Edison Company.—Mr. W. A. Kreidler in full Control of the Western Electrician.—Discussion of Continuous Currents vs. Alternating Currents by the Chicago Electric Club.—Dullness in the Electrical Supply Trade.—Rumored Purchase of Van Depoele Interests by the Thomson-Houston Co.—The Bell Telephone Co. of Missouri.—The Missouri and Kansas Telephone Co. Mr. Dorsett Still Engaged on Underground Schemes.—The City and Suburban Telephone Co. of Cincinnati.—Electric Light Wire Privileges in Cincinnati.—The Cincinnati Centennial Exhibition. —A Westinghouse Plant Ordered for St. Louis.—The Inter-State Telephone Co.—The Electric Light at Defiance, O.

THE Chicago Edison Company now announces officially that on or about May 1st lights will be supplied from the central station on Adams street to the district bounded by Franklin, Lake, State and Van Buren streets. This comprises the heart of the business part of Chicago, and there will be no difficulty for the Edison company to find a market for its 20,000 lights if the prices are low enough. It can be predicted with confidence, however, that the plant will not be in operation by May 1st, 1888, nor for some time thereafter. The building and machinery will not be ready by that time, although the work is now being vigorously pushed forward.

Mr. W. A. Kreidler has secured entire control of the *Western Electrician*. Under Mr. Kreidler's management his paper has made a remarkable success and has already established itself as an institution in which the electrical fraternity of the west particularly take a pride and interest.

The following announcement was sent out on March 2, by the secretary of the Chicago Electric Club :—The board of managers of the Chicago Electric Club have arranged for a discussion which will bear the general title—"The Continuous Current *vs.* the Alternating Current." Among those who will participate in the discussion are : Mr. H. Ward Leonard, of Leonard & Izard, representing the Edison system, who will advocate the continuous current; Mr. M. M. M. Slattery, of the Fort Wayne Jenney Electric Light Co., who will uphold the alternating current; Mr. E. P. Warner, of the Western Electric Co., who will argue for the continuous current; Mr. F. B. Badt, of the United States Electric Lighting Co., who will espouse the cause of the alternating current. The discussion will be inaugurated at the regular meeting of the club, Monday evening next, March 5th, by Mr. H. Ward Leonard, who will read a paper entitled "The Comparative Value of the Continuous and Alternating Current Systems for the Commercial Distribution of Electricity from Central Stations."

The success of this series of papers is shown by the largely increased attendance at the meetings of the club this month. The seating capacity of the club rooms has been completely occupied for the first time in the history of the club, and the interest in the discussions is such as to compel the chairman to terminate the debate abruptly when the hour for closing arrives.

It is reported by those engaged in the electrical supply and manufacturing business that trade is dull. Telephone companies are inclined to restrict orders to immediate requirements pending the announcement of the decision of the Supreme Court in the Bell patent. It is to be expected that electric lighting business will fall off at this season of the year, and an important factor in all branches of electrical trade is the high price of copper which materially restricts consumption. Since the syndicate (which now has control of the copper market) has secured the product of the Calumet and Hecla mines, confidence in an early return to moderate prices has ceased. It is evident that the syndicate has now absolute control of the copper market, and as it gives evidence of remarkable financial strength and seems to meet with some success in getting the general public interested in copper as an article of speculation and thus secures assistance in carrying its load, it would not be surprising if the price of copper should be higher than now, and it seems likely that the price will go no lower for some time. But with the immensely increased output from nearly all the mines in the world, and the largely reduced consumption resulting from the high prices, it is safe to predict that *some time* there will be a crash in the copper market.

It is announced that the Thomson-Houston Electric Co. has purchased the patents and stock of the Van Depoele Electric Manufacturing Co. At latest reports the bargain had not been completed; but as the Van Depoele company announces it there seems to be no doubt of the trade going through. As the most valuable part of the Van Depoele business is in the direction of electric motors and railways, this consolidation would seem to foreshadow increased activity in that line on the part of the Thomson-Houston Electric Co.

Mr. George F. Durant, general manager of the Bell Telephone Company, of Missouri, states that his company has secured a favorable lease of a building lot, and purposes following the example of New York, Chicago and Louisville in putting up a telephone building in St. Louis.

Mr. W. W. Smith, general superintendent of the Missouri and Kansas Telephone Company, reports a continuance of the remarkable growth of the exchange in Kansas City. Mr. Smith also claims that the Kansas City exchange has the best record as to the number of connections per operator per day. An absolutely accurate count gives the highest number of *completed* connections in 10 hours at 1659 for one operator, taking care of 100 subscribers.

The indefatigable Dorsett is now in Kansas City working for an underground ordinance. Numerous gas explosions have occurred recently in the Dorsett conduit in Chicago, fortunately without serious results.

The City and Suburban Telegraph Association of Cincinnati has the reputation among telephone people of giving good service at low rates and of keeping on good terms with the public. If proof of this were wanted it is furnished in the remonstrance signed by 90 % of the subscribers of the telephone company asking the Legislature not to meddle with the rates charged for telephone service. Public sentiment is so opposed to the bills now pending in the Ohio Legislature with reference to telephone rates that it is almost certain these bills will be defeated, as were similar bills which were introduced at the last session.

The Board of Public Works, of Cincinnati, is considering an ordinance granting to any electric light company the right of way over streets, alleys, and public grounds in Cincinnati, on condition of payment to the city of one per cent. of the company's gross revenue. It is predicted on good authority that this ordinance will pass.

The Centennial Exposition, which will open at Cincinnati on July 4th, will be lighted by 350 arc lights and 2,000 incandescent lights. The management has not decided yet what systems to employ.

The Excelsior Electric Light Co., of St. Louis, has ordered a 5,000 light Westinghouse alternating plant.

The Inter-State Telephone Co. has failed to secure the franchise for which it asked in the City of Chicago.

The Defiance Electric Light Co., Defiance, O., has decided to put in a United States alternating system.

CHICAGO, March 20, 1888.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, 115 *Nassau street, New York city.*

ANTHONY AND BRACKET'S PHYSICS.

[89]. To the excellent reply of Mr. Jackson (In March *Electrical Engineer*) to criticisms on this Text Book of Physics, I wish to add the test of actual use, where it was designed to be used, in the college class-room. I have a class which has nearly completed the part on magnetism and electricity, and with some knowledge, from use, of several English, French, and American text books, I find Anthony and Bracket's the best for instruction in scientific and technological courses. I. THORNTON OSMOND.

State College, Pa., March 15, 1888.

THE JACK-KNIFE SWITCH.

[90]. It is sometimes amusing to read the errors of history, and trace the channel through which facts are discolored or mangled before their assuming a crystalized form. The hatchet and cherry tree story of good old father Weems, the fall of Newton's apple, the Tell and Gessler fable, all, with many another romance, are among the innocent fibs that, like Jack the Giant-Killer and the German fairies, go to make up the personnel of literary history. But when an author sets himself up as authority in matters of exact knowledge, in the line of science or mechanics, and lets his imagination lead him into romancing, the value of his work becomes, to say the least of it, rather doubtful.

The history of the Jack-knife switch, as well as the switch itself, was made in Chicago. The switch was a necessity to the system of telephone board in use by the American District Co., and the invention was more a matter of growth than of invention, and cannot be claimed by any one individual. It was the final outcome of several attempts to accomplish the transfer of the subscriber's line from the board to the operator's telephone, and had no less than two or three distinct forms before it was finally considered complete.

The invention has been claimed by two or three parties, and among these was a Canadian Frenchman, who at the time was superintendent of construction for the A. D. T. Co., which company opened the first exchange in Chicago. The knowledge of this claim of Mr. Rousseau was all that the story alluded to in the ELECTRICAL ENGINEER had for bottom facts The Parisian author unable to comprehend what a "Jack-knife" is, rounded out the innocent little fiction by assuming that Mr. Rousseau's front name was Jack. In justice to all concerned, it is but fair to say to-day that Mr. Scribner was principal inventor, while Rousseau was undoubtedly there as well as Scribner and others, and ready with suggestions of a practical nature, although his name is not Jack but Hector. C. C. H.

Chicago, March 22, 1888.

LITERATURE.

REVIEWS.

The Storage of Electrical Energy: BY GASTON PLANTÉ. Translated from the French by Paul Bedford Elwell. London: Whittaker & Co., 1887.

THE Planté lead battery has been a familiar subject in physical and electrical text books for upward of a score of years, and although the theory of its action was thoroughly understood, it was more than a decade after its discovery that an improvement by Camille Faure, in the method of preparing the plates, attracted universal attention to the practical utility of this remarkable cell. Previous to this improvement, although Planté had exhibited its unusual calorific effects, the battery had remained a sort of scientific curiosity, and, apparently had never been adapted to any commercial use; but it contained the germ of a serviceable instrument and, like many another well-known principle, only awaited a demand for its services to develop its practical worth.

The introduction of electric lamps, which required currents of greater quantity than could be conveniently and economically produced by the ordinary voltaic battery, created this demand; and the secondary battery emerged from the laboratory to enter the workshop, where the dynamo had already arrived.

From 1859 to 1879 M. Planté made hundreds of cells of his lead battery, and performed numerous novel and beautiful experiments by their aid. The results of his researches were given to the world in memoirs contributed to the Académie des Sciences, or published from time to time in various scientific periodicals. In 1883 these memoirs, after being considerably abridged and revised to include more recently discovered phenomena and applications, were collectively published in book form in Paris under the title of "Recherches sur L'Electricité," a demand for a better knowledge of the author's labors having, no doubt, been created by the much heralded improvement of Faure. The subject of this review is a recent English translation of the above work.

There are abundant examples of the akwardness characteristic of so many translations throughout the book, often resulting in obscurity. There is a rather long table of "errata," but on the whole the text is clear and concise. The book is divided into six parts treating respectively of: I—The Accumulation and Transformation of the Energy of the Voltaic Battery by means of Secondary Currents. II—Applications. III—Effects Produced by Currents of High Tension. IV—Analogy with Globular Lighting. V—The Rheostatic Machine. VI—Analogy Between Electrical Phenomena and Effects Produced by Mechanical Actions.

According to the auther, Gautherot, a French scientist, was the first to discover that platinum or silver wires which had been used to decompose saline water, possessed the property of generating currents of short duration after being disconnected from the battery. These so-called secondary currents were first observed in 1801, soon after the discovery of the voltaic battery. Many other scientists subsequently investigated voltaic polarization, as it was then termed, studying chiefly the currents obtained with platinum electrodes. In 1859 Planté undertook to compare the secondary currents produced by voltameters of various metals in different solutions, and although his apparatus as well as his methods would now be considered very crude—for instance he took no account of the internal resistance of batteries or voltameters—he produced the battery which bears his name, and much valuable information about re-action currents which these memoirs record.

The first chapter studies the secondary currents produced by different voltameters of the more common metals in acid and alkaline solutions, and the attending phenomena during and after the passage of a current is minutely described in a very thorough and instructive manner. At the outset, however, the reader who is familiar with the subject as it is understood to-day, is surprised to find that while the author acknowledges the probability of the absorption by, or even combination of hydrogen with the negative electrode of a platinum voltameter, as a partial cause of the prolongation of the secondary current, and goes so far as to presume that the hydrogen forms unstable combinations with the electrolyte, he deliberately attributes the cause of the same action in a lead voltameter wholly to the oxidation of the negative electrode. Now when a current is passed through a lead voltameter for a considerable length of time the positive electrode not only becomes visibly oxidized but so deeply that it turns almost black; when discharged, on the contrary, the negative electrode is only slightly discolored and even a casual observation will show that it is only very lightly oxidized. In view of the fact that Planté comments on his observation of these very points, it certainly seems strange that he should fail to perceive that the slight oxidation of the negative electrode is entirely insufficient to account for the quantity of the secondary current. It seems to be generally conceded at present, however, that the capacity of secondary elements is largely due either to a combination of hydrogen with the negative lead electrode or else to its occlusion within it. It is perhaps worth notice in passing that this same blunder has found its way into a paragraph descriptive of the secondary battery, in the recently published Physics of Anthony and Brackett.

The second chapter describes the several forms which Planté gave to his secondary elements and the best methods of forming and charging them, besides containing much information relating to maintenance which is applicable to batteries of the modern type. It seems strange to read here the statement that these secondary cells are well adapted to running motors *for a short time only*, when the author has already pointed out that the duration of the secondary current depends upon the thickness of the oxide which in turn is only limited by the thickness of the plates. Although later on he instances having charged cells with a Gramme hand magneto, it is evident that his dependence upon the ordinary small and expensive galvanic battery for charging them, was the factor which prevented him from recognizing the adaptability of his battery to supplying current in a large scale years before it was actually accomplished. The imperfect knowledge of the relation of electrical quantities to each other, possessed by prominent physicists only a few years ago, is well illustrated by a passage in this chapter to the effect that the quantity of electricity has more importance than its potential when opposed by external resistance. The duration and constancy of secondary cells are also investigated, as well as their efficiency and ability to preserve their charge. The analogies between their action and the effects produced by static condensers are also considered.

The second part of the work describes many practical applications of the secondary battery such as to galvanocausty,

illuminating cavities in the human body, firing mines, electric brakes, and even to electric arc lighting "for several minutes only."

The first chapter of the third part of the work deals with the effects produced by currents of high tension. Many curious and remarkable phenomena are described, which, however, would be similarly produced by high tension currents from any other source. The second chapter of this part illustrates a method of engraving on glass by electricity; and a very ingenious suggestion is made for a rock drill in which electric discharges are to disrupt the rocks.

The fourth part of the work discusses the analogies between the effects previously described and various natural phenomena, chiefly of a meteorological character, which leads to several interesting theories regarding such phenomena. The fifth part describes the once celebrated rheostatic machine, and the marvellous effects which it is capable of producing. This machine, which consists of a large number of small condensers arranged with a commutator, by means of which they may be charged in parallel and discharged in series, was designed by Planté for the purpose of transforming the energy of the voltaic battery so as to obtain an electromotive force equal to that of electrical machines. The sixth and last part of the book discusses some of the results obtained with these high tension currents, leading to mechanical analogies which suggest an interesting theory regarding the nature of electricity.

The first part of the book is undoubtedly a valuable contribution to the history of the evolution of the secondary battery, and is full of useful information regarding the nature of the chemical actions which arise in such batteries and of the fundamental principles underlying them. The remainder of the work is interesting and instructive, as the records of the labors of original experimenters always are.

CATALOGUES AND PAMPHLETS RECEIVED.

The United States Electric Lighting Co.—Western Department—C. C. Warren, manager, Chicago, send us a very clever and interesting circular recently issued. It contains a large number of letters from purchasers and users of the apparatus of the United States company, expressing their satisfaction with the performance of their plants in very complimentary terms. These letters are reproduced in fac-simile—reduced in size, and not only constitute a valuable tribute to the excellence of the electric lighting outfits of the company, but form (excluding those type-written) a rather interesting collection of specimens of Western chirography, several of which are uncommonly handsome. The covers are decorated with a series of pictures outlining, in a quietly humorous fashion, the history of illuminants.

Not the least striking feature of the circular is found in the object lessons on pages 26 and 27, the former exhibiting pictorially the gradual darkening of the globes of "competing" lamps, and the latter showing diagrammatically the growth of the business of the Western Department of the United States Electric Lighting Co., since its commencement in 1883.

The Brooks Underground Telegraph Construction Co., Limited, Philadelphia, issue a pamphlet of 17 pages, announcing their readiness under Patent No. 356,981, dated February 1, 1887, to grant, license, or contract to lay underground electrical conductors for every kind of service, and to guarantee the highest insulation and durability. The principal features of underground construction offered by the Brooks company in this pamphlet are the use of iron pipe as a conduit, and resin and resin oil as insulator and filling. Tables of a number of tests are given, showing high insulation with low inductive capacity.

The Lithographers' and Photographers' Directory, contains a complete list of all firms connected with lithography, photography and the graphic arts in the United States, Canada, Mexico, Central and South America. The book is published by The Lithographer Publishing Co., Fred Buehring, Pres't and Treas., at 12 Centre street, New York; price $3.

ELECTRICAL NEWS AND NOTES.

ANNUAL REPORT OF THE AMERICAN BELL TELEPHONE CO.

OFFICE OF THE AMERICAN BELL TELEPHONE COMPANY,
BOSTON, March 27, 1888.

To the Stockholders:

The business of the company for the year 1887 has been, on the whole, satisfactory.

The receipts for royalties show a reasonable increase; and the licensed companies, with few exceptions, have improved and extended their plant.

The statistics are given in the following tables:—

EXCHANGES.

—	1883.	1884.	1885.	1886.	1887.	1888.	Decrease from 1887.	Increase over 1887.

EXCHANGE CONNECTIONS.

The estimated number of exchange connections daily in the United States is	1,011,517
Or a total per year of	369,203,705
The number of daily calls per subscriber varies in different exchanges from 3 to 14, the average throughout the United States being	6 37-100
As compared with	5 82-100

the number reported last year, an increase of 9 per cent.

The average cost to the subscriber varies according to the size of the exchange and character of the service, from 2 to 8 cents per connection.

EXTRA-TERRITORIAL CONNECTIONS.

The average daily number of extra-territorial connections is	6,796
Or a total per year of	2,480,540
The extra-territorial earnings for the year amounted to	$565,718 46
Of which this company's share is	76,076 36
An increase over 1886 of	459 06

In the case of five companies which have not reported December earnings, the amount is computed at the average of the previous 11 months.

The treasurer's statement shows—

Gross earnings from all sources		$3,453,027 70
Expenses		1,242,430 89
Net earnings		$2,210,596 81
Miscellaneous credits		27,011 31
Total		$2,237,608 12
Regular dividends paid	$1,176,252 00	
Extra dividend paid	392,084 00	
Total dividends	$1,568,336 00	
Reserve for depreciation of instruments	132,616 38	$1,700,952 38
Balance to surplus account		$536,655 74
Surplus account, Dec. 31, 1886		1,491,380 18
Total surplus		$2,028,035 92

The so-called government case, begun in January, 1887, came up June 18 for argument on our demurrer to the bill of complaint, and on September 26 the court sustained the demurrer and dismissed the bill. The government has taken an appeal to the Supreme Court, and a motion to advance the case for speedy hearing was made in October, upon which there has as yet been no decision.

The Globe Telephone Company, owning the Meucci claim, was finally enjoined in July. This case has also been appealed to the Supreme Court.

The case against the American Cushman Company is now ready for final hearing, and the directors have every reason to expect a favorable result.

In the cases before the United States Supreme Court on appeal (Dolbear case, Drawbaugh case, Molecular, Clay and Overland

cases, which, it will be remembered, were argued the latter part of January and the first of February, last year) a decision was rendered on the 19th March current. The opinion was by Waite, Chief Justice. All the cases on all points are determined in favor of the company.

The scope of the patent for which we have contended was sustained by the court. Mr. Justice Bradley, in behalf of himself and Justices Field and Harlan, expressed an oral dissent on the question of fact concerning Drawbaugh's priority of invention. Otherwise the opinion of the court expresses the unanimous opinion of all the members of it.

Bills for the regulation of telephone rates have been again introduced in a number of state legislatures, but the result of the Indiana legislation has been so unsatisfactory to the subscribers, and the inexpediency of so crippling the companies that they would not be able to give the best possible service is so obvious, that we may hope that no such measures will be adopted.

The committee appointed by the legislature of the State of New York to investigate telephone charges has reported a bill limiting rates for combination line service in cities of over 1,000,000 inhabitants, but the report of the committee itself furnishes the best arguments against the passage of such a bill, recognizing, as it does, the great cost of underground work, and the frequent changes in switch-boards, cables, etc., made necessary by the rapid strides in electrical inventions.

The long-line service has been extended from New York to Albany, and to Boston, making a total of 550 miles of pole lines and about 10,000 miles of wire.

The success electrically, as well as commercially, has been beyond our expectations.

The income from the long lines is now more than sufficient to meet the current expenses, and there is every reason to expect that before next year it will pay a moderate profit. The great cost of the plant is to be borne in mind in considering the direct profit from the long-line service, but the importance of the system as a safeguard to our business cannot be overestimated.

It is intended to complete this year the lines between New York and Boston, to extend from Albany towards Buffalo, and to build a line from Chicago to Milwaukee. The estimated cost is about $1,000,000.

The patent division has continued its work of collecting, digesting and studying information upon electrical matters, and preparing reports upon questions submitted to it by officers of the company.

It has also during the year considered and passed upon specifications for inventions for which the Western Electric Company intend applying for patents.

The electrical division has been mainly occupied in investigation for the accumulation of technical information for the use of our counsel. It has also begun, and is now pursuing, a series of experiments on multiplex telephony and on simultaneous telephony and telegraphy.

The mechanical department has experimented with a large number of instruments sent to it for examination, and it has also given much time to experimentation with a view to the improvement of our standard instruments, and to the solution of the problems which have been brought out by the long-line service.

Considerable time has also been spent in the study of magneto transmitters and in devising different forms for local uses.

On the first of September the company suffered a serious loss in the resignation of the president, Mr. Forbes. At a subsequent meeting of the board of directors the following resolutions, reported by Messrs. G. G. Hubbard, Cochrane and Sanders, a committee of the directors, were unanimously adopted, and ordered to be presented to the stockholders:—

"*Whereas* our associate, Mr. Forbes, was chosen president of the National Bell Telephone Company at its organization on the 11th of March, 1879, and continued in that office until the merging of that company into this the American Bell Telephone Company, and has been the president of this company since its organization in April, 1880, to the date of his resignation, in September, 1887; and

"*Whereas* during this long service the telephone business has grown in a most remarkable manner, the net income having increased from less than $2,000 per annum to about $2,200,000, and the number of instruments in use from about 21,000 to 375,000; and

"*Whereas* the vast and unparalleled litigation which this company has been forced to undertake, and the many and various interests occasioned by the system of licensing persons and corporations in every part of the country, and the intricate relations with the Western Union Telegraph Company and others have demanded qualities of an unusual character; and

"*Whereas*, Mr. Forbes has given constant attention to the interests of this company, and has displayed eminent ability, great dignity, uniform fairness, courtesy, and great tact in grasping the main points of the questions that have come before him, and has thereby won the confidence of his associates, of the licensees of this company, and of those with whom he has been brought officially in contact; and

"*Whereas*, Mr. Forbes, by these qualities, as well as by the marked moral courage and pluck exhibited on several trying occasions, and by his excellent judgment, has largely contributed to the success of this company;

"*Therefore resolved*, that the thanks of the directors be and they hereby are given to Mr. Forbes; and that this preamble and resolution be recorded in full in the minutes of the board, and a copy be presented to the stockholders at the annual meeting of this company.

"GARDINER G. HUBBARD.

THE TELEPHONE INVESTIGATION.

THE NEW YORK ASSEMBLY COMMITTEE'S REPORT.

The committee appointed by the New York Legislature in April, 1887, to investigate the business of telephone companies in the state, presented a report March 6th, 1888.

The committee find that the American Bell Telephone Co. is a corporation organized under the laws of Massachusetts with a capital of $10,000,000, which owns and controls all patents now in use upon telephonic instruments in the United States. Except as a large stockholder in local companies, it does not operate in this state. It does not sell any of the instruments manufactured under its patent, but leases them to its licensees at an annual royalty of $14 per set, excepting the Metropolitan company of New York and the Commercial company of Troy, which it charges $10, reserving the right to increase all these royalties. In addition to these royalties it also exacts from its licensees a

further consideration in the form of a donation of 35 per cent. of the capital stock of its licensees. It also exacts a commission upon an extra territorial and telegraph business done by the licensees of 15 per cent. of the former and 50 per cent. of the latter.

In respect to companies in the vicinity of New York, the committee finds that the Westchester Telephone Co. operates portions of Westchester and Rockland counties, and was organized in 1882, and has a capital stock of $300,000, all of which has been issued and $100,000 of which is owned by the American Bell company as franchise stock. Its cost of construction is $372,196.07, and its net earnings for the past fiscal year were $13,937, showing a percentage of net earnings to cost of 3.7 per cent. The remainder of its stock has all been purchased by the Hudson River company. Its average dividend since organization has been two per cent. It has 1,006 subscribers.

The Staten Island Telephone Co. operates Staten Island, and is a sub-licensee of the Metropolitan company. It was organized in September, 1883, having a capital stock of $135,000, all of which has been issued. Its cost of construction is $81,586.58; its net earnings for its past fiscal year were $6,474, showing a percentage of net earnings to cost of 7.9 per cent. The Metropolitan company own $45,000 of its capital stock, issued to them as franchise stock.

Its annual dividend has been five per cent. It has 272 subscribers paying from $60 to $120 per year, depending upon distance from central office.

The New York and New Jersey Telephone Co. operates Long Island, Brooklyn, Jersey City, and outlying points. It was organized in 1883 with a capital stock of $2,400,000, all of which has been issued. It is a sub-licensee of the Metropolitan company which owns $800,000 of its stock. Its cost of construction is $1,709,000, and its net earnings during the past fiscal year were $185,766, showing a percentage of net earnings to cost of 10.8 per cent. It has 5,317 subscribers, at an average rental of $70.56. This company has a special class of service furnished to 65 subscribers who are large users, at an increased rate of $720 per year. One subscriber, by actual count, has 18,000 connections with New York city alone, aside from his local use of the instrument. Another found by actual record kept, that his telephone was used four hours and 30 minutes out of seven business hours, counting from the moment it was being connected with subscriber to the moment it was released. "These instances illustrate the inequity of a state uniform rate," says the report. These cases exist to a less marked degree throughout the state.

The Metropolitan Telephone and Telegraph Co.: The committee review the conflict between the Western Union Telegraph Co., as owners of the Edison patent, and the Bell company, as owners of the Graham Bell patent, out of the settlement of which grew the Metropolitan company, of New York. This company was organized in May, 1880, with a capital stock of $1,000,000, owned respectively by the American Bell company of Boston, and the Western Union Telegraph Co. in the proportion of 60 and 40 per cent. It operates Manhattan Island only, although the territory operated by the Westchester company, the Staten Island company and the New York and New Jersey company was originally embraced in its franchise. The royalty paid by the Metropolitan company to the American Bell company is $10 per instrument per annum. Its cost of construction is $1,871,116.94, $426,729 of this having been expended in the erection of the company's new building at No. 18 Cortlandt street. This the committee have disregarded in basing its percentages, upon the ground that it had not been occupied during the time embraced in its receipts and disbursements, and thus had not contributed towards its net earnings. Its net earnings for its past fiscal year were $576,055,80, showing a percentage of net earnings to cost of 39.88 per cent. It paid no dividends in 1881 or 1882, and the dividend for its past fiscal year was 10 per cent. Its earnings for the year ending March 31, 1886, were: Private lines $187,737.31, district exchanges $800,072.50, telephone rentals $108,212.76, tolls $60,548.75, miscellaneous sources $15,222.64, total $1,171,793.96. Its expenses were: Operation $458,151.71, reconstruction $48,654.-43, instrument rental, American Bell Telephone Co., $165,758,27; rental Manhattan plant, $16,500; rebates, $1,750,79; roof rentals, $6,745.88; taxes, $12,000; insurance, $3,000; legal expenses, $13,-500; miscellaneous, $2,315.19. Total, $728,376.27. Their average number of subscribers for the past year was 6,101, at an average annual charge of $149.83

The total number of subscribers to telephone exchanges throughout the state is 26,240. The total capital stock of the companies doing business in the state is $8,395,000. The total cost of construction of the plants of the various companies throughout the state is $5,780,978.43. The total net earnings for the past fiscal year were $1,028,233. The average capitalization per subscriber is $319.93. The average capitalization throughout the United States is $351 per subscriber.

The committee deal at length with the problem of underground construction, which they have met in Brooklyn, Buffalo, and New York. They present an exhaustive brief summarizing the federal and state decisions in a large number of states, upon the right of the legislature to regulate the charges of local companies, and find that they have such right; also, upon the right of the legislature to regulate the royalty charged by the American Bell company, of Boston, and find that they have not the right to regulate them. The committee review the investigations in Rhode Island, Connecticut, Maine, New Hampshire, New York, Pennsylvania, Ohio, Michigan, Minnesota. Illinois, Indiana, Iowa, Arkansas, and Texas, with regard to this question, and review at length the legislation upon this question in Indiana, and its effect both upon the companies and the people. They treat of the various patents owned by the American Bell company, and the interference between the caveats of Mr. Berlimer and Mr. Edison, arriving at the conclusion that, at the option of the American Bell company, its present monopoly upon telephonic instruments for practical use will extend for a period of 17 years from the date of the settlement of this interference. The only means to defeat this monopoly will be the invention by another person of a telephone which shall render communication possible by means of what is known as the "make and break" system, which, electricians say, is extremely doubtful.

The committee think there is but one circumstance which in their judgment would justify legislative interference; that is the imposition of a charge so large that it shall be a burden to those who use the telephone, and which shall produce a revenue disproportionate to that return to which its inventors and those who put their money into it when it was an unsolved problem are entitled. That circumstance is found in the cities of New York and Troy; in the case of the latter its franchise expires so soon that no legislation is recommended for that city. They believe the returns of the Metropolitan company are larger than they have a moral right to demand, and submit a bill making the charge in New York city $6.50 per month, with an added mileage of $2 per month for all points exceeding one-half mile from any one of its present central offices.

Two bills accompany the report of the Telephone Investigation Committee. The first limits the issue of stock and creation of lines by incorporated companies, and is as follows:

Sec. 1. No share or shares, stock or certificate of stock shall hereafter be issued by any company organized or chartered by or under the laws of this state, except upon previous payment in cash of the par value thereof, or upon condition of service equivalent in value to par value thereof. A record shall be kept by each company of all payments for stock which shall show in detail the date and amount of each payment, the kind, amount and value of the service rendered for which any stock is issued, the amount of stock issued, where and to whom; which record shall be open at all times to stockholders of and any person dealing with such company for inspection.

Sec. 2. No bond, mortgage, or other evidence of indebtedness shall be issued, given, or made whereby any lien upon any of the property of any company created or incorporated by or under the laws of this state is, or is assumed to be, created, until a statement in writing has been made and duly verified by the oath of the president, secretary and treasurer of the company, or a majority thereof, showing that the capital stock of such company has been actually paid in, and such statement so verified has been filed in the county clerk's office, where the principle business of such company is transacted; and any wilful misstatement or false statement contained therein shall be perjury, and punished as such.

Sec. 3. Any officer or other porson who shall issue or assume to issue any share, stock or certificate of stock, or who shall make or execute any bond or mortgage; or cause any indebtedness whereby any lien is or is assumed to be created, contrary to the provisions of this act, is guilty of a misdemeanor, and upon conviction liable to a fine of not more than the par value of the stock or shares issued or lien created, or assumed to be created, or by imprisonment in the county jail for not more than one year, or by both such fine and imprisonment.

Sec. 4. This act shall take effect immediately.

The second bill regulates telephone charges in cities of 1,000,-000 or more inhabitants, limiting the price of instruments within one-half mile of the central office in such cities to $6.50 a month, with $2 a month additional for each additional half mile of distance. A penalty of $50 is provided for every violation of the law. The act to take effect June 1st.

AN EXTENSIVE ISOLATED PLANT.

The reconstructed building of the Equitable Life Assurance Society at 120 Broadway, New York, now nearly completed, has been fitted with an isolated incandescent electric light plant, which is probably the largest one in the world. It will be remembered that in this building some of the first, if not the very first, incandescent lamps ever seen in New York city were put in service by the United States Electric Lighting Co.

The steam and electric plant is located in the basement of the building in a spacious apartment fitted up in a neat and substantial manner, with concrete floors and walls of glazed tiling. The steam plant comprises one 500 h. p. Corliss engine for general service, and a 75 h. p. Armington & Sims engine for special and night service; nine boilers, each of 100 h. p. capacity, supply steam for operating the electric plant and running the elevators and pumps, as well as heating the entire building.

The electric current for lighting is supplied by a group of seven 600-light Weston dynamos, which ordinarily are separately excited by an independent dynamo, although switches are so arranged that their field circuits can be detached if emergency requires from the independent dynamo, and connected either with the main leads or with any particular dynamo of the system. The general field circuit of all the dynamos is controlled by an automatic regulator.

The building is wired for 7,000 16-candle incandescent lamps.

These are arranged upon six main circuits, which are carried through the elevator shafts, and are connected by feeders with the main switchboard in the dynamo room. The local branches on each floor are concealed within the walls, and usually carry about 30 lamps each. The fall in potential is calculated not to exceed 2 per cent. when the full number of lamps are in service.

Some idea of the dimensions of this plant may be gathered from the fact that it has more than half the capacity of the Pearl street central station of the Edison Illuminating Co.

The complete and thorough manner in which this immense installation has been carried out, as well as the brief time which has been occupied in the work are deserving of special commendation. The entire plant and fittings were supplied by the United States Illuminating Co. of this city.

THE HERZOG TELESEME ADOPTED BY THE NEW YORK POLICE COMMISSIONERS.

The Herzog teleseme system for police signaling has been on trial in the Nineteenth Precinct, New York, ever since last August, and, in voting, March 8, to adopt it for general use throughout the city, the police commissioners cited the fact it has been subjected to working tests in all kinds of weather, and is the only system that fully meets all the requirements of the service.

Mr. F. Benedict Herzog, the inventor, is to be congratulated, not only upon his ingenuity in devising and perfecting his system, but also upon the success which has crowned his energetic and persistent work in securing the adoption of the teleseme for the police service of New York.

AN INGENIOUS MESSAGE-HOOK AND LETTER-FILE.

The Harpoon Security Message Hook, illustrated below, seems to be a very clever device for filing telegraph messages or letters. It has been recently introduced by The E. S. Greeley & Co., New York..

The illustration requires little if any explanation. The security device in this hook consists of a gravity barb or tongue pivoted at one end, which drops naturally into the position shown in the engraving. In filing a paper on the hook, the barb or tongue is forced up into a slot and allows the paper to slide freely along the hook, making only a small round hole without tearing it. When the paper is in position the barb falls again into its normal position, preventing the paper from heing pushed or blown off the hook.

Convenient accessories of this sort add much to the comfort and despatch of office work.

PERSONAL MENTION.

MR. EDWARD P. THOMPSON, patent attorney and consulting electrician, is *not* dead—but alive, well and busy, spending a considerable part of his time in correcting the impression, which seems to have spread far and wide, that he was the E. P. Thompson reported killed in the recent railroad accident in Georgia.

THE BOSTON ELECTRIC CLUB.

Nearly 100 members of the Boston Electric Club sat down to a bountiful supper at the Thorndike last evening. After doing justice to the viands, several musical selections were rendered by a quartet from the Bell Telephone company. President Alexander then introduced Mr. Thomas D. Lockwood, chief of the electrical and patent department of the American Bell Telephone Company. who read an interesting paper, entitled "The Inevitable Anticipation" At its conclusion, President Alexander called upon Mr. Charles Dutton, secretary of the house committee of the New York Electric Club, who criticised humorously the paper of the evening. Mr. A. H. Chapman then took the chair and called upon Messrs. Cleverly, of Philadelphia, Pierce, of Boston, Wright, of Springfield, Rev. Mr. Cleveland, of Malden, Mr. W. J. Denver, and others.—*Boston Herald.*

THE PHILADELPHIA ELECTRICAL SOCIETY.

The committee on experiments and tests of the Philadelphia Electrical Society are engaged in making preliminary experiments, and obtaining data for their final tests upon the various electric protectors submitted to them by the inventors.

MANUFACTURING AND TRADE NOTES.

THE EAST RIVER ELECTRIC LIGHT CO. offer factory and storage room in New York city to manufacturers of electrical appliances. Their station, covering 10 city lots in East 24th street, is seven stories in height and substantially constructed. It is designed to make it a centre for electrical manufactures of all kinds, and 1,500 h. p. can be supplied day and night.

MESSRS. A. U. ALCOCK & CO., Melbourne, Australia, whose advertisement will be found in our columns, offer their services to intending American exhibitors at the forthcoming Melbourne Centennial Exhibition.

THE HILL CLUTCH WORKS, Cleveland, O., were awarded first prize, a bronze medal, by the American Institute of New York, for their exhibit at the annual fair last autumn.

THE WESTINGHOUSE ELECTRIC COMPANY have purchased the United States patents for Professor George Forbes' electric meter, and will manufacture them on an extensive scale for its own use.

THE CALLENDER INSULATING AND VULCANIZING CO. have sent out a new price list, under date of January, 1888. Their list embraces a large variety of electric conductors for many purposes. In addition to their Bitite wires and cables, they offer their Trinidad insulation for electric light conductors and other similar uses.

THE American Institute have awarded the medal of superiority to the Jerome Kidder Manufacturing Company, No. 820 Broadway, New York, for their exhibit of "Electro-Medical Apparatus Appliances and Instruments" at the fair of 1887. For fifteen consecutive years the Jerome Kidder machines have received the highest awards from the American Institute. Their large elaborately finished cabinet battery, unique in design, attracted much attention.

ELECTRIC STREET RAILWAYS IN AMERICA.

Now in Operation.

Worcester, Mass.—Worc. & Shrewsbury—(To be changed from steam to electricity); 2.7 mi.; g. 3; overhead cond. DAFT.

Notes.

After many months spent in experimenting with and investigating motors for street railways, the Lindell Railroad Company, of St. Louis, using Washington avenue and other streets in that city, on Feb. 10 finally adopted electricity as the motive power for their road. The motor adopted is a combination of the Julien storage battery and the Brush machinery. One car has been in constant operation during the week and has given entire satisfaction, and the whole equipment of the road will be fitted out with the motor as soon as the necessary work can be done.—*N. Y. Times.*

IT is understood that the contract for the ten new electric cars which are being built for the Fourth Avenue line in this city provides for the delivery of so much power per car at a certain price, and this price is about forty per cent. below what the same power would cost furnished by horses. Julien storage batteries will be used, and it is expected that the ten cars will all be ready for use this spring.

THE new electric railway in Richmond, Va., which was equipped by the Sprague Electric Railway and Motor Company, of New York, is working successfully under very trying conditions, and is attracting favorable notice.

LEGAL NOTES.

UNITED STATES CIRCUIT COURT.—SOUTHERN DISTRICT OF NEW YORK.

The Holmes Electric Protective Company against *The Metropolitan Burglar Alarm Company.*

Patent to Holmes and Roome, No. 120,874 is for the change in the location of the protective electric lining from the inside to the outside of a safe. Question of patentability considered.

To find a new position for an old device is not patentable, unless a new result is produced.

The invention claimed in the patent sued on was described but not claimed, in a patent issued to the same patentees before the application for the patent sued on was filed. Held, that where a patent fully described an invention which could be claimed therein, and makes no reservation, and gives no warning to the public, a second patent granted upon an application filed some months afterwards, which claims simply and solely the invention thus made public is invalid. Cites and follows Mahn *vs.* Harwood.

Two years publication of an invention is not allowed an inventor before applying for a patent. An abandonment to the public cannot be recalled.

The addition of features, not found in the earlier patent, to the second patent could not bolster up the second patent as to the parts shown in the earlier patent. Guarantee Insurance Co. *vs.* Sellers.

INVENTORS' RECORD.

Prepared expressly for THE ELECTRICAL ENGINEER, *by* Pope, Edgecomb & Terry, *Solicitors of Patents for Electrical Inventions*, 11 *Wall street, New York city.*

CLASSIFIED LIST OF UNITED STATES ELECTRICAL PATENTS.

From Feb. 21, to March 13, 1888 (inclusive).

Alarms and Signals:—*Conductor for Electrical Fire-Alarm Systems*, W. A. Barnes, 378,078. *Electro-Magnetic Bell*, J. and S. Wetzler, 378,124, Feb. 21. *Electric Ship Signal*, J. W. Dooley, 378,876. *Police, Fire and District Telegraph*, E. T. Gibson, 378,927. *Fire-Alarm Signal Box*, A. A. Smith, 378,983. *Burglar Alarm*, C. H. Wright, 379,144, March 6. *Fire-Alarm Signal-Box*, G. M. Stevens, 379,339. *Device for Returning Signals in District Telegraph Systems*, W. V. Lockwood, 379,404, March 13.

Conductors, Insulators, Supports and Systems:—*Telegraph Cable*, W. R. Patterson, 378,175, Feb. 21. *Test-Box for Underground Electric Wires or Cables*, R. S. Waring, 378,560. *Conduit for Electric Wires or Cables*, same, 378,561. *Underground Conduit for Electrical Conductors*, M. R. Muckle, Jr., 378,801. *Man-hole Chamber for Underground Electrical Conduits*, same, 378,802, Feb. 28. *Insulator*, L. M. Neal, 378,971, March 6. *Underground Conduit*, M. R. Muckle, Jr., 379,406. *Telegraph Wire*, W. Hewitt, 379,535, March 13.

Clocks:—*Machine for Regulating Time-Pieces*, W. B. Farrar, 379,511, March 13.

Distribution:—*System of Electrical Distribution by Secondary Batteries*, J. S. Sellon, 378,115. *Alternating Current Transformer*, R. Kennedy, 378,320. *Transformation and Distribution of Electric Energy*, same, 378,321, Feb. 21. *System of Electrical Distribution*. Conant & Latshaw, 378,452. *System of Electric Distribution*, T. Spencer, 378,787. *System of Electric Distribution*, same, 378,788, Feb. 28. *Continuous and Alternating Transformer*, F. Jehl, 379,073, March 6.

Dynamos and Motors:—*Core for Dynamo-Electric Machines*, W. C. Rechniewski, 378,375, Feb. 21. *Self-Exciting Alternate Current Electric Generator*, O. A. Moses, 378,456. *Regulator for Electric Generators*, W. S. Hill, 378,547, Feb. 28. *Magneto-Electric Machine*. O. P. Loomis, 378,892. *Dynamo-Electric Machine*, O. Urban and M. J. Wightman, 379,037, March 6. *Dynamo-Electric Machine*, L. C. Rice, 379,284. *Apparatus for Dressing off the Commutators of Dynamo-Electrical Machines*, D. J. Tittle, Jr., 379,344. *Regulation of Electric Motors*, D. Higham, 379,466 and 379,467, March 13.

Galvanic Batteries:—*Galvanic Battery*, H. Walter, 378,121; Walter & Marsh, 378,122, Feb. 21. *Battery Vessel*, J. Wiest, 378,484, Feb. 28. *Carbon Battery*, G. E. Terrell, 378,943. *Depolarizing Compound*, A. F. W. Partz, 379,180, March 6. *Non-Polarizing Constant-Current Battery*, F. J. Crouch, 379,372. *Primary Electric Battery*, H. Woodward, 379,551 and 379,552, March 13.

Ignition:—*Electric Gas-Lighting Apparatus*, C. W. Holtzer, 378,677, Feb. 28. *Electric Gas-Lighter and Extinguisher*, G. L. Hogan, 379,396, March 13.

Lamps and Appurtenances:—*Manufacture of Incandescent Electric Lights*, T. Mace, 378,258. *Incandescent Electric-Lamp Fixture*, H. M. Doubleday, 378,358, Feb. 21. *Arc Light*, L. N. P. Poland, 378,616. *Air Pump*, H. J. Doerr, 378,666. *Double-Arc Lamp*, Wightman and Rasmussen, 378,818, Feb. 28. *Incandescent Lamp Socket*, F. Thone, 379,255, March 13.

Metallurgical:—*Working Metals by Electricity*, N. De Bernados, 379,453, March 13.

Miscellaneous:—*Automatic Temperature Regulator*, W. S. Johnson, 378,187. *Display Stand for Non-Magnetic Watches*, A. C. Smith, 378,339. *Process of Treating Peat*, S. Heinman, 378,395, Feb. 21. *Automatic Electric Photographing Apparatus*, E. N. Bliss and J. F. Middleton, 378,426. *Electrical Stop-Motion for Steam-Engines*, R. Exley, 378,668. *Apparatus for Bleaching by Electrolysis*, E. Hermite and C. F. Cooper, 378,681. *Bending Electrotype Plates*, J. B. Miller and J. Dale, 378,707. *Machine for Forming Type-Bars*, C. Mergenthaler, 378,797, Feb. 28. *Pole Changer*, E. M. Hamilton, 379,062. *Electrical Contact Maker and Breaker*, C. Lambdin, 379,074. *Electrical Apparatus for Dental Operations*, C. A. Eisenhart, re-issue, 10,907, March 6. *Coupling for Joining Electric Wires*, C. Hering, 379,221. *Automatic Electric Spacing Mechanism for Type-Writers*, J. F. McLaughlin, 379,406. *Apparatus for Electric Bleaching*, E. Hermite and C. F. Cooper, 379,465. *Switch for Electric Light and Motor Circuits*, F. W. Brann and G. I. Kinney, 379,501. *Pneumatic Carrier*, G. D. Burton, 379,503. *Test-Circuit and Apparatus for Electrical Cables*, I. H. Farnham, 379,532, March 13.

Railways and Appliances:—*Electric Railway*, C. T. Mason, 378,259, Feb. 21. *Electric Railway Station Indicator*, G. Guntz, 378,440. *Rail-Connection for Electric Railways*, E. L. Orcutt, 378,517. *Automatic Electric Air-Brake*, J. F. Carpenter, 378,657, Feb. 28. *Apparatus for the Propulsion of Cars by Electrical Energy*, A. H. Bauer, 378,864. *Electric Railway Car-Brake*, W. M. Schlesinger, 378,980. *Electric Railway*, W. W. Hopkins, 379,069, and 379,070. *Spring-Jack for Electric Railways*, S. H. Short, 379,081, March 6. *Bell-Cord for Cars*, W. Glascow and S. S. Stevens, 379,459. *Electric Surface Railway*, J. A. Enos, 379,509, March 13.

Storage Batteries:—*Secondary Battery*, M. Stecher, 378,629. *Automatic Switch for Secondary Batteries*, J. S. Sellon, 378,527, Feb. 28.

Telegraphs:—*Printing Telegraph*, D. E. Pike, 378,107. *Multiple Telegraphy*, C. Selden, 378,181. *Telegraph Key and Instrument*, W. A. Melbourne, 378,332, Feb. 21. *Printing Telegraph*, P. B. Delany, 378,436 and 378,437. *Telegraph Repeater*, L. Russell, 378,464. *Relay-Magnet*, E. L. Orcutt, 378,552, Feb. 28. *Electric Telegraph*, D. Kunhardt, 379,016. *Telegraph Instrument*, E. M. Hamilton, 379,060. *Telegraph Sounder*, same, 379,061. *Telegraph Key*, same, 379,063. *Telegraph Sounder*, same, 379,064. *Telegraphic Repeater*, J. Kolzer, 379,203, March 6. *Telegraphic Pen*, H P. Copeland, 379,368, March 13.

Telephones, Systems and Apparatus:—*Mechanical Telephone*, N. B. Stubblefield and S. C. Holcomb, 378,183. *Telephone Switch*, J. R. H. Hinton, 378,250. *Telephonic Transmitter*, M. G. Farmer, 378,298. *Telephone Receiver*, A. W. Brown, 378,385, Feb. 21. *Lock-Out Box and Shunt-Circuit for Telephone Exchanges*, C. H. Haskins, 378,679. *Telephone*, Ehrlich, Dubinski and Rein, 378,780, Feb. 28.

THE

ELECTRICAL ENGINEER.

Conducted by F. L. POPE AND G. M. PHELPS, JR.

PUBLISHED MONTHLY BY

THE ELECTRICAL PUBLISHING CO.,

11 Wall Street, New York city.

TERMS OF SUBSCRIPTION.

United States and Canada, per annum,	$3.00
Four or more Copies, in Clubs (each) "	2.50
One Copy, Four Months,	1.00
Great Britain and other Foreign Countries within the Postal Union "	4.00
Single Copies, -	.30

[*Entered at the Post Office at New York, N. Y., as second class mail matter.*]

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of the* ELECTRICAL PUBLISHING CO. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 11 *Wall Street, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. VII. NEW YORK, MAY, 1888. No. 77.

NOTICE OF REMOVAL.

THE ELECTRICAL PUBLISHING CO., publishers of the ELECTRICAL ENGINEER—remove their offices May 1, from 115 Nassau street to 11 WALL STREET, New York.

SPECIAL NOTICE.—To afford an opportunity to become acquainted with **THE ELECTRICAL ENGINEER,** *the publishers will send it to any new address for* THREE MONTHS *for* FIFTY CENTS.

The publishers have pleasure in announcing that by arrangement with the WESTERN ELECTRICIAN *of Chicago, they are enabled to offer that able Western exponent of Electricity together with the* **ELECTRICAL ENGINEER,** *for one year to new subscribers for* $5.00. *To those of our present subscribers who desire it we will supply the* WESTERN ELECTRICIAN *one year for* $2.50

THE PATENT REFORM BILLS.

WE print elsewhere in this issue the bills for amending some features of the organization of the patent system prepared by the legal committee of the National Electric Light Association, and now before the House Committee on Patents. These bills, as our readers are already aware, are directed, one to the creation of a Court of Patent Appeals, and the other to increasing the permanency and efficiency of the office of Commissioner of Patents. A third bill, known as the Atkinson bill, dealing with the present vexatious limitation of United States patents by foreign patents of prior issue, was found before Congress by the committee of the Association, who will favor its passage with some changes of detail, which, we believe, have not yet been perfected.

These measures, substantially in their present form, have been presented in the columns of the ELECTRICAL ENGINEER, and other electrical journals, on several occasions during the past year, together with the very able arguments in their support of Mr. Arthur Steuart, chairman of the legal committee of the Electric Light Association, and others. They receive cordial support on all sides among men who, through their business or profession, are brought into close relations with the patent system. Among other endorsements is that of the Chicago Electric Club, which has adopted a series of resolutions commending the bills and urging their adoption. We are informed that the Court of Patent Appeals bill has been most favorably commented upon by several of the Justices of the United States Supreme Court, including the late Chief-Justice. So far as we have learned, no objections or unfavorable criticisms of either measure have been put forward. That the Court bill would greatly simplify and expedite patent litigation seems to be generally conceded ; and there can hardly be less doubt of the advantage to be derived from the passage of the Commissioner's Office bill. By increasing the dignity and importance of the office and adding to its stability, it may fairly be expected to bring about a more settled condition of the rules and regulations under which patents are granted.

It is to be hoped that the authors of these measures will continue to receive hearty support, and that all who appreciate their scope and bearing will take pains to communicate with the legal committee of the National Electric Light Association, 213 East German street, Baltimore.

THE INSTITUTE OF ELECTRICAL ENGINEERS.

THE annual meeting of the Institute for the election of officers, presentation of reports and miscellaneous business, will be held at 127 East 23d street, New York (House of the American Society of Civil Engineers), May 15th. The general meeting for the reading and discussions of papers will be held at the same place on May 16th. The papers already announced are as follows :—

"Some Old and New Applications of Alternating Currents," by Lieut. F. Jarvis Patten, U. S. A. "On Compensated Resistance Standards" and "On Professor Moler's 'Swinging Arm' Galvanometer" by Professor Edward L. Nichols, of Cornell University. Papers on "Subterranean Electrical Systems," by Professor George W. Plympton, and on "The Possibilities and Limitations of Chemical Generators of Electricity," by Francis B. Crocker, will also be presented. Papers have been promised by foreign members, the subjects of which can not be given at present.

The work of the Institute has steadily grown in interest and value. The published transactions of the annual meetings and of the monthly meetings of the last two seasons mark a very satisfactory and gratifying advance. The increase in membership since the last annual meeting has proved far in excess of the expectations of the council, and it still goes on.

As might be expected of an American technical society, the work of the Institute, in its papers and discussions, has been of a noticeably practical kind; often directly and entirely so, and nearly always, when partly or wholly theoretical, closely related to practical work. Of work "in the air" leading no-whither, there has, happily, been little if any.

The forthcoming general meeting promises to succeed worthily the May meeting of last year.

THE TELEPHONE PATENTS AGAIN SUSTAINED.

The suit which was brought by the American Bell Telephone Company against the Southern Telephone Company, last fall, to restrain the latter company from infringing the Bell patents, was decided by Judge Brewer, at Little Rock, Ark., on April 21, in favor of the complainant. A writ of injunction was immediately served upon the officers of the Southern company in Little Rock, where it has about 500 instruments in use. The enterprise was owned by Little Rock parties, and the plant is said to have cost about $53,000. As the decision is, in some respects, an important one, we have printed it in full in our present issue.

It is rather unfortunate that the gentleman "just returned after a two years' sojourn" in India, where, he believes, the telephone "dates back fully 2,000 years," did not get here in time to tell us all about it before the United States Supreme Court decided that Professor Bell was the real inventor.

A column and-a-half is given by a weekly electrical contemporary to an account of what Mr. Amesbury, with "an English officer named Harrington," saw and heard of ancient telephones in India. It appears that only "high caste" natives use telephones, and not only confine their use to the service of their temples, but have successfully kept their existence a secret until very recently. Besides telephones, they have real subways; underground conductors in wooden conduits being found by Mr. Amesbury and "Harrington" connecting temples several miles apart. The conducting wire was of some mysterious metal, the nature of which the observers were unable to determine, though they were quite sure it "was neither steel, copper nor brass." The telephones examined were found to have "been in use for thirty years. The priests were very old men, and they remembered that the line of communication had been renewed only once during their incumbency. They showed us the remains of worm-eaten transmitters and wooden conduits that must have been hundreds of years old." No mildewed remains of a subway commission are mentioned among the finds. The narrator further says: "In every part of India and in Burmah this system of secret communication exists, although hundreds of travelers have never suspected it"

We trust that Mr. Amesbury and his friend "Harrington" were not piloted around among the Indian temples by Madame Blavatzky and Colonel Olcutt. If, as we strongly suspect, the whole yarn be a little joke by some wag on the staff of our clever and often amusing contemporary, we trust its publication has raised no false hopes of re-opening the appealed telephone cases, and throwing the telephone open to the public.

That fatal or serious accidents from electric light circuits are mostly if not wholly preventable is perfectly certain. They still occur, though not frequently. Carelessness on the part of the victims is sometimes the cause, but too often it is to be found in the absence of proper precautions and safe-guards in the construction and management of central stations and circuits. The personal equation of carefulness on the part of linemen and lampmen should be practically eliminated. Wherever sure protection can be provided, it should not be permissible to trust to the cautiousness of employés. These remarks are suggested by the case of Ameron Kratz, a lamp-trimmer, who was permanently disabled by a shock received while in the performances of his duties on a high tower at Detroit. It is alleged that he received the shock from a wire which he had been told was "dead." He brought suit against the local electric light company for $25,000 damages. The jury awarded him $10,000. The company pleaded Kratz's negligence in their defense. We have seen none of the testimony in the case, but whatever the merits may be between Kratz and the company, the verdict suggests an additional incentive to manufacturing and operating electric light companies not to stop short in the very general improvement that is going on in the construction and operation of plants until they are quite sure they have exhausted all known means of ensuring immunity from death or bodily injury to all who handle or use electric lights.

Under the title, "Gilbert's Fables," Mr. T. Commerford Martin contributes to the *North American Review*, for April, a striking and very interesting article, bringing together an enumeration of the results reached in the leading electrical arts and industries, from the telegraph, now but 50 years old, to electric light and power, the products of the last 10 years. The telephone dates but 12 years back. The aggregate of capital and labor already employed in the manufacture and service of the machinery and apparatus of these new electric arts, as indicated in Mr. Martin's paper, is almost surprising, even to those acquainted with these applications of electric science. Mr. Martin happily introduces his subject by quoting Lord Bacon's somewhat contemptuous allusion to Dr. Gilbert as "telling so many fables" in his now famous work, "De Magnete," and throughout the article intersperses many apt allusions and illustrations, drawn from his wide and generous acquaintance with general literature.

Those who disapprove the Board of Electrical Control and all its doings, may take some solace in the prospect of some more fun from the Mayor and Mr. Gibbens. Mr. Hewitt promptly resumed his nagging of Mr. Gibbens at the first meeting of the board this season, while that energetic and vivacious young gentleman was no less ready to re-open hostilities. Whatever we may get in the way of conduits and conductors, the Mayor's incisive questions and caustic comments, together with Mr. Gibbens's bumptious alertness, are quite sure to supply some diversion for the long summer months. Meanwhile, might it not be prudent for Mr. Gibbens to keep a sharp eye out for bears on his way home nights?

WHILE in this country the Knights of Labor and other workingmen's organizations are petitioning Congress for government telegraphs, the publication in England of the Postmaster-General's report, showing the receipts and expenditure of the telegraph service of Great Britain since its acquisition by the state, is causing popular discontent with the series of annual deficits which have to come out of the tax payers.

There is something absurd in the attitude of the Knights of Labor on this question. Probably more than nine-tenths of the telegraphing in the United States is done by people who pay in the aggregate less than one-tenth of the taxes, and who constitute a still smaller fraction of the population—that is to say, by those engaged in conducting the manufacturing, commerce and journalism of the country. A government telegraph service at rates materially less than those now prevailing, must inevitably result in losses which would have to be made good from taxes. Do the workers for wages really want to help pay for the telegrams of the merchants, manufacturers, bankers and editors of the country? Or has their movement its real origin in a fancy that it will in some way strike at the pocket-books of Mr. Jay Gould and other capitalists?

THE development of electric lighting interests in England, which has been so greatly retarded by unfavorable legislation, may be to some extent stimulated by the passage of the County Government Bill before Parliament, which would transfer the present onerous control of electric lighting franchise from the Board of Trade to local authorities. Commenting on this subject in a recent number, *The Electrician*, of London, says:—

If the County Government Bill should pass into law in the shape now before the House, the powers at present exercised by the Board of Trade in connection with the granting of provisional orders under the Electric Lighting Act, will be transferred to the new County Councils. It may fairly be presumed that, on the whole, such a change would operate favorably upon the development of electric lighting. Time will certainly be saved, legal expenses would probably be diminished, and a wider local interest would be aroused in the undertaking.

USEFUL knowledge, immediately applicable to their work, is always gratefully received by electricians. The following is from the "Practical Information" column of an esteemed contemporary:—

Galvanic Cell.—The cell contains zinc in an alkali. The polarization is prevented, not by oxide of copper, but by oxide of mercury, which, by dissolving in the alkaline solution, amalgamates the zinc. In order to increase the surface it may be mixed with iron shavings.

IN the suit of the Consolidated Electric Light Co. against the McKeesport Electric Light Co. (Edison system) for alleged infringement of the Sawyer-Man filament patent, Judge Acheson, of the United States Court, Western District of Pennsylvania, has dismissed the demurrer of defendants, and ordered the filing of an answer to the complaint. The issue of this suit may be expected to clear up much uncertainty and perplexity as to the relations of incandescent electric light patents, and the respective rights of several companies.

THE Underground Conduit franchise granted by the Boston board of aldermen, described in our Boston correspondence, was promptly vetoed by Mayor O'Brien—on the opinion of the Corporation Counsel that it was illegal.

OBSERVATIONS.

THE observer has been reading the Rules and Requirements of the New England Insurance Exchange, adopted March 1, 1888. They are 73 in number, mostly excellent, and represent the long stride which practical men have taken towards a working knowledge of the force which we term electricity.

The rules as a whole are so good, that only four of them stand out from the others either as "bright particular stars," or as "occultations."

These are respectively the 20th, 34th, 61st and 70th. The first and third of this quartette, are noticeable chiefly for the evidence they afford that the incisive arguments of Brother I. N. Miller, are returning after many days; *underwriter's wire* being specified as something which must not be used in *damp* places; where ammonia vapors prevail, or for pendants. The covering of the said wire is still, however, frequently dignified by the term "insulation."

The 34th rule is the problem of the list. Rosin as a flux is prohibited, and a preference for an acid solution not stronger than 10 per cent. is manifested. The writer has several times been asked the reason of this rule, but he would prefer to undertake the solution of "The Lady or the Tiger," or the "Discourager of Hesitancy."

The expert who evolved the rule in question, will doubtless explain that the average man cannot make a good job of a joint when he uses rosin as a flux, or at all events doesn't; to which the rejoinder might fairly be made that such a man should not be allowed to make joints or splices at all, for he will surely forget to wash off the superfluous acid. It would be better to stick to the resin.

As to rule 70; the test required by it may answer very well, when the circuit to be tested is very short, or has but few branches; but it would hardly be trustworthy on a very long circuit; as a magneto machine will ring its own bell on an open circuit with an electrostatic capacity which is quite low.

* * *

THE daily press is always interesting when it touches on scientific subjects; it is also frequently amusing and occasionally instructive. When a subject is on the *tapis* which in addition to its scientific interest involves questions of a legal character, the boldness with which it is tackled by the average scribe, excites in our breasts an involuntary admiration, of an intensity to which we have been strangers, since the time when in the days of boyhood we were wont to peruse with thrilling awe, the final 11 pages of our school dictionaries, wherein was recited the story of the bearding by Theseus of the Minotaur in his lair.

These observations are suggested by the comments of the secular and religious daily and weekly papers upon the lately delivered telephone decision.

Space will not permit a report of even the most striking here; but one or two deserve and require at least passing comment.

One statement which appeared in a number of papers—and which started out as a Washington despatch is the following:

"The Supreme Court has sustained the broad fifth claim of the *company* * * * which seems to make it impossible now for any person to secure a valid patent for a speaking telephone," then the author of the despatch exhibits his knowledge of patent law—continuing, "It would seem, therefore, that American ingenuity must direct itself *for the remainder of the 14 years of the original patent to some other channel than in attempting to invent improvements in the method of transmitting* AUDIBLE *speech by electric wires.*"

Another newspaper Solon—(this time the Boston *Watchman*, a religious denominational organ) comes out with the following statement of fact. "Not only is priority of invention declared, but exclusiveness also. One of the cases, that of Amos E. Dolbear, related to an invention distinct from that of Alex. G. Bell, it being a magnet telephone, with a magnet, coil, and armature, while the Bell invention operates by static attraction, by means of metal plates opposed to each other."

Perhaps, however, the funniest pronunciamento is that of a Rochester, N. Y., newspaper, which says that "there is still hope

for the public. None of the telephone cases on which the court has delivered judgment, presented the *Reis* defense, which was, therefore, not considered. The government case now to be brought, will for the first time introduce the publications regarding the Reis telephone, which will furnish evidence absolutely irresistable."

• • •

WHAT has "current-jelly" to do with electricity? Until recently, nothing. But from this time, henceforth and forever, that sublime accompaniment of broiled quail and roast duck is to be associated with voltaic batteries—*vide* United States patent issued January 31, 1888, for a chromic acid battery. The inventor first (so he says in his specification) dissolves chromic acid in water, and then adds sulphuric acid and stirs; mineral wool or asbestos is then gradually added, and the mixture now reaches its maximum heat. As it again grows cool, it is changed into a jellied mass.

The patentee, with profound knowledge of human nature, then goes on to surround his battery with a captivating interest calculated to rouse curiosity and desire in the public to try his battery (after which they will, of course, use no other) by saying that this jelly he has called "electric current jelly."

• • •

THE electric light companies and lighting apparatus manufacturers of New England, have begun a good work in the organization of "The New England Electric Exchange."

The proposition to issue licenses to properly qualified persons, as also the gradation of licenses, would seem to be admirably adapted for the improvement of construction, for the prevention of casualties, and for elevating all classes of men connected with electric lighting. Now let the exchange continue in the way it has begun, by seeing to it, that the examiners appointed are men regarding whose opinion no doubt can arise, and who are thoroughly practical themselves. The value of a license, will in no slight degree depend upon the known qualifications of the examiners or licensors.

• • •

It appears from the public prints that the Boston board of aldermen has voted, after several hearings, to grant certain petitioners an ordinance conferring the exclusive right for a term of years to lay and maintain conduits for electric wires in the streets of that city.

The various electric companies doing business there do not (if appearances may be trusted) seem to relish the idea.

Nor do the daily papers take kindly to the notion of an exclusive license for this privilege. Always excepting the *Herald*.

The last mentioned paper has been interviewing persons who are supposed to have opinions on such matters; and it is, in fact, a published account of one of these interviews that attracted the attention of the observer. A practical electrician who has charge of a large electric light plant, but who desired that his name should not be used, said:—"The talk about not being able to carry the electric light, and telephone and telegraph wires in the same conduit is all moonshine. *Suitably insulated, there would be no danger of induction.*"

It is a pity the practical electrician would not consent to the publication of his name.

• • •

A MEMOIR of Fleeming Jenkin, the well-known electrician has been written by that most versatile author, Robert Louis Stevenson. All electricians will do well to add this to their libraries. Very little is said in it about electricity, but by its perusal one finds that Jenkin, though one of the busiest of men, and though filled with enthusiasm for his work, was good as well as great; was permeated with a wide humanity and an overflowing charity for all; and was, withal, of a homelike and home-loving disposition. Books like the memoir of Jenkin, and the biography of Clerk Maxwell are invaluable, as leading us to a better understanding of the men, and consequently of their technical works. Mr. Stevenson is to be congratulated upon his success as a biographer, and has shown that he can shine with equal brilliancy in his new role, as in that of a novelist, poet, or essayist.

ARTICLES.

DATA FOR WINDING COILS.

BY SCHUYLER S. WHEELER.

THE spaces occupied by insulated magnet wire of the various sizes when wound in solid coils, including the average irregularity actually found in practice, are given in the following table in the form in which they can be used most conveniently in calculations, together with all the resultant data of weight, capacity of coil per inch, &c., that are required in designing electrical machinery.

To determine the size of wire which may be used in winding a coil, it is generally necessary to take the diameter of any wire from the common wire tables, add the estimated thickness of the insulation, add a trifle more to cover the occasional failure to wind the convolutions close together, and with this estimated size as a basis, compute the number of turns which can be wound in a given coil, making allowance also for the gain of space caused by the turns of wire of each outer layer falling into the spaces between the turns of the under layers. And if the number of turns of the coil or its resistance and other elements are not satisfactory, it is necessary to repeat the same operation with another size of wire.

The laying out of coils is of constant recurrence; and these dimensions, namely, the spaces required for wires, have always been so unsettled, that it occurred to the writer to try to reduce the drudgery of electrical engineering by settling them once for all by test; putting the results in shape for convenient use, and publishing them after the manner of the specific gravities of substances. The table was made according to this plan, and gives all of the dimensions and data of single cotton covered magnet wire when closely wound in a coil, not as estimated but as they *are*. That is, the figures given are each the average of several coils actually wound, and they therefore include what would be called allowances for probable error when guessing the thickness of the insulated wire. The figures or constants given, having been derived from coils actually wound and reduced to the basis of an inch, will give exact results within extremely close limits when multiplied up to the dimensions of any coil. For the purpose of ascertaining very accurately the number of turns of wire to the inch down to one decimal place, a great many large coils, including coils wound with nearly every size of wire from No. 4 to No. 30, were very carefully measured both in length and depth of wire, and the number of layers and turns of wire counted. In each case several observations were made by different men on different coils of the same size wire, and the results averaged. The number of turns was then divided by the inches of length, giving the number of turns per inch of length of bobbin. These figures are in the first column of the table. The number of layers on the trial bobbins was then divided by the depth of the wire on the spools, carefully determined, giving the number of layers per inch, and these results were then averaged. It was necessary to reduce these to layers per inch before averaging, because the coils under observation were wound to different thicknesses. These values make the second column of figures in the table. Both sets have been carried out to the second decimal place, so that when multiplied by a number of inches in designing a large coil the error will fall below one convolution if possible.

The third column represents the number of turns of wire to the square inch of cross-section of coil, or, in other words, the number of turns which could be got on a spool one inch long and one inch deep on all sides. This was obtained by simply multiplying together the two preceding values, namely the number of turns per inch in the layer, and the number of layers per inch of depth of coil. The accuracy of the three columns was then checked by measuring the square inches of cross-section of the coils on which the ob-

servations were made, and multiplying in the turns per square inch according to our third column to see if it agreed with the total number of turns on the observed coils.

To illustrate the use of these figures let us find what size of wire we must wind on a magnet, whose winding space is three inches long and one inch deep, to get one thousand turns on the magnet. There are three square inches of space in the section of the spool (on one side) therefore each square inch must take 333 turns of wire. Looking in the table of turns to the square inch we find No. 16 nearest, giving 324 turns, therefore No. 16 wire wound on the magnet would give 972 turns in the given space, while No. 17 would give three times 378 or 1134 turns. Of course it is understood that the steps of increase of diameter between consecutive standard sizes of wires produce corresponding abrupt steps in all the data of the table, and that this cannot be avoided without special intermediate sizes.

To illustrate the use of these values, let us find what size of wire we must wind on a magnet, one inch in diameter, whose winding space is three inches long and one inch deep on each side, in order to get 20 ohms resistance. Calculating the space for wire in cubic inches, as in the ordinary way of determining the volume of hollow cylinders, by subtracting the volume of the central inner cylinder formed by the magnet itself, from the total volume of the spool, we find that there are 18.8 cubic inches of space for wire on the spool, therefore each cubic inch must have $\frac{20}{18.8} = 1.06$ ohms. Looking in the column of ohms to the cubic inch we find that No. 21 is the nearest size giving .98 ohm. Multiplying this by 18.8—the cubic inches of space—we find just what resistance this wire will give when the coil is wound.

In the same way if we have a helix of 500. ohms resistance, and we wish to rewind it to have 400. ohms resistance, without figuring its cubic inches of wire space, we simply

TABLE OF SPACES OCCUPIED BY WIRES OF DIFFERENT SIZES, WITH SINGLE COTTON INSULATION, TOGETHER WITH DATA OF THE COPPER.

* Estimated.

† Calculated on the basis of Dr. Matthiessen's standard, viz.: 1 mile of pure copper wire of 1-16 in. diam. equals 13.59 ohms at 15.5° C. or 59.9° Fahr.

The next column gives the feet of wire in a coil, per cubic inch of spool space. This is obtained by dividing the figures in the last column by twelve, since if there are one hundred turns or strands in a square inch of spool space, there are one hundred inches of wire in a cubic inch of the same winding. While the preceding column of turns per square inch settles the magnetizing capacity of a coil, this last column is of equal importance because it is the key to both the weight and the resistance of any coil of any size of wire.

The next column gives the resistance per cubic inch of wound wire, and enables us to compare instantly the respective resistances of spools full of different sized wires, or to predetermine the resistance of a coil. It is obtained by multiplying the preceding column, or the feet per cubic inch, by the ohms per foot of the wire.

look in the column of ohms per cubic inch of wound coil and see what wire has to each cubic inch, four-fifths of the resistance of the wire already on the helix. Then when wound with that wire the coil will have four-fifths of the resistance it had before, because the cubic inches of wire will be the same in both cases, and the specific resistance giving capacity of the insulated wires when coiled are in the ratio of four to five per unit of volume.

The next column gives the weight per cubic inch. This item is necessary to determine the weight of wire which will be required for a given coil. The figures were obtained by weighing the wire used on the observed coils and dividing by the cubic inches of their respective spaces, and was corroborated at some points by multiplying the feet of wire per cubic inch by the feet per pound of wire, weighed and measured.

The last column under insulated wires gives the feet of wire of each size per pound, as stated in the catalogues of the wire manufacturers, and as tested.

To these are added some of the more important columns from the ordinary wire tables in order that all requisite data of the conductor itself, carrying capacity, resistance, etc., may be obtained for any calculation without keeping another table at hand. These values are well known and explain themselves.

There is also added a column giving the proportion of solid copper in any given volume of winding. This is obtained by multiplying the number of turns of wire to the square inch, by the circular mils or area of section of the bare wire, which gives the amount of metal which can be got into each square inch of space, or the percentage of metal in any coil. This is important as showing the efficiency of the winding or the inefficiency of the insulation. It is be noticed that a bobbin wound with No. 4 wire contains about twice as much metal as the same bobbin wound with No. 30. This shows why the weight per coil per cubic inch (as given in the column of weight per cubic inch), decreases with decrease in the size of wire.

The value of all of these figures is that they are as accurate as the variations of wire and of the work of different men in winding will permit, being the average of a great many helices which have come under the writer's observation in the regular course of manufacture, and which are therefore more likely to be of the average quality, and free from the favor of special care. Being all reduced to a standard of one inch the data is in shape to be applied directly to any helix or spool large or small, by simply multiplying it by the corresponding dimensions of the helix in inches.

Three quarters of the calculating—all that is dependent upon the wire—is done permanently, and preserved ready to be "mixed for use." There remains nothing but to fit the data to the spool,—to multiply the unit amount per inch, square inch, or cubic inch, as the case may be, by the size of the coil.

The simplest use of the table is to ascertain the correct wire for a coil wound on trial and found to be wrong. For example, if it was wound with No. 14 wire, but is then found to require twice as many turns, it is easy to glance down the column of turns to the square inch and see what wire makes twice as many turns in a square inch as does No. 14. It falls between No. 17 and No. 18. These sizes of wire will therefore give nearest to double the number of turns when wound on the coil. Similarly if the resistance of the coil is to be made seventy-five per cent. greater we can look in the column of resistances to the cubic inch, for the size that will give seventy-five per cent. more resistance than No. 14. It is found to be No. 15.

If we have a spool of a fixed size and must put a thousand turns on it, we measure the section of the winding space on one side and find how many turns we must wind in each square inch of that section, by dividing the inches of cross-section of spool space into the thousand turns, and then taking this quotient or the required number of turns to each square inch, look for that number of turns to the square inch in the table. If, however, the wire must be of a certain size to carry the current we are limited on the size of wire, but we may read the number of turns to the square inch for that wire and, multiplying by the inches of section of the coil, we find the number of turns we can have in the given coil with this wire.

The column of weight of wire per cubic inch of coil gives us the means of telling at once what the weight of any coil will be when wound with any size of wire, or, what is the same thing, what will be its cost for copper. The weight of any helix may be predetermined by multiplying the cubic inches of wire space on the spool by the weight per cubic inch of the wire that is to be used.

Perhaps a good way of showing the usefulness of the table is by calling attention to the fact that the figures give the respective properties, resistance, weight, turns, etc., of each size of wire, per unit of space, or "specifically," so that they are all on a common basis for comparison; and that it gives all of these as they are after being affected by the insulation, average goodness of coiling, etc., etc., including all of the defects that are met with in regular practice, so that calculations based upon the figures will be as near as possible to the results as found in the coil when it is made.

As all the figures in each of the columns refer to a common unit amount of wire space, they indicate upon comparison the exact rate at which the capacity of a helix will change in each respect, as the wire on it is changed from one size to another. If the wire on a helix is changed from one size to another, the helix will be changed in each respect exactly in the ratios of the figures opposite the two sizes of wire in question. Exact correctness and agreement of figures based upon such variable quantities as unspun cotton, crooked wires, and varying tightness of winding, is not to be expected, but reasonable accuracy is of great practical value, and is attained in the table. In fact it is surprising how closely alike quantities of coils of each size of wire turn out in the long run. It was thought at first from unsatisfactory experiences in trying to estimate turns for coils, that the irregularities were so variable that a satisfactory table could not be constructed, but it was found that in practice the coils of each size run about the same every time, notwithstanding the use of wire manufactured in different places, winding by different men, and the use of different qualities of insulation. The conclusion was that poor success in estimating the turns that can be got on a bobbin, by guessing at the way that the wire will probably wind, is not so much due to the unreliability of the wire as to the impossibility of telling just how much the turns will fit into each other, how much the insulation will compress, etc., etc., without trying it. The facts that insulation is usually rejected if it varies beyond certain limits as unfit for use, and that a thick insulation will compress more than a thin one in winding, account partially for the regularity of windings. Slight variations from the standard in the sizes of wires is a more serious cause of error, as the wire is not compressible. In using the tables it will be necessary to make allowance for this when occurring, as the tests were made upon wires of standard size.

The writer will be grateful for correction of any material error in the table, or any suggestion to increase its usefulness.

DISCUSSION OF THE PRECISION OF MEASUREMENTS.[1]

BY SILAS W. HOLMAN, S. B.

Assistant Professor of Physics, Massachusetts Institute of Technology.

(Continued from page 49).

Significant figures. By a significant figure is meant any digit other than zero. By places of significant figures will be meant places which properly may contain significant figures; *i. e.*, places other than those where zeros are used simply to enable the position of the units place to be indicated, as when zeros are prefixed to significant figures in a decimal fraction, or suffixed to them when significant figures are not known for all the places down to the units. The decimal point is simply a conventional sign to indicate the units place, and its position in no way indicates or affects the number of significant figures or the fractional accuracy of a result. Thus, for instance, to say that a distance was measured to 0.1 mm. gives no indication of the number of places or the fractional precision, unless we know what the whole distance was. Suppose that this was about two meters. Then the frac-

tional precision would be the same; viz., one in 20,000, whether written as 2 m., or 20 dm., or 2000. mm., or 0.002 kilom. And in computations involving this distance, six places of significant figures would be retained, independent of what unit it was originally expressed in. Rules for the rejection or retention of places of significant figures in data and computations may be deduced from the principles already presented. They are important for the avoidance, on the one hand, of waste labor and a delusive or ludicrous display of figures, and on the other to insure to the computed result all the accuracy to which it is entitled by the data.

Let M be an original observed quantity and δ its average deviation. Let that place of figures in M which corresponds to the second place of significant figures in δ be called the rth place. The average deviation by its derivation denotes that M is uncertain on the average by an amount δ. For instance, if $\delta = 0.034$, then M on the average is uncertain by three units in the $(r-1)$th pace; *i. e.*, in the place corresponding to the first significant figure in the average deviation, and in the rth place by 34 units. In general, the first significant figure in the δ may be anything from 1 to 9, as the case may be; hence in general M is uncertain by 1 to 9 units in the $(r-1)$th place, and by 10 to 90 (or strictly 10 to 99) in the rth place. Thus the digit in the $(r-1)$th place in M is always somewhat uncertain, and that in the rth place is very uncertain. It is useless, therefore, to retain significant figures in M beyond the rth place, and when the δ is large even this place is of little use. Also two places of significant figures in any δ are all that are of any use, since the only service of the δ is as an index of the precision of its quantity M,—or, stated in another way, because, as may be seen by inspection, the second and subsequent places of significant figure in any δ are very uncertain.

Thus anything which affects a quantity M beyond its rth place is wholly negligible, and in all ordinary work any effect less than $0.1\ \delta$ is sufficiently small to be neglected, for M is of itself uncertain on the average by ten times this amount. Let us adopt, then, as the basis of rules for significant figures, the condition that the accumulated error arising from the rejected places of figures must not at any stage of the computation exceed that corresponding to $\frac{1}{10} \cdot \frac{\delta}{M}$ when this has its *minimum* value. This will be quite close enough for all physical work, except possibly of extreme refinement, and will give rules which may be applied to data of seven or less places of figures, and which may be occasionally relaxed, *with judgment*, in ordinary work. Let the rules be framed for giving the number of *places* to be retained, as this gives the greatest convenience in practice. Now the minimum value of $\frac{1}{10} \cdot \frac{\delta}{M}$ would be that where the first two significant figures in δ were respectively 1 and 0, and in M were 9 and 9; *e. g.*, $\delta = 0.010$, $M = 9.999$. For this case $\frac{1}{10} \cdot \frac{\delta}{M}$ would be $\frac{1}{10000}$th, corresponding to unity in the rth place of M. Then the *accumulated computation error at any stage* must not exceed 1 unit in the rth place of figures. The errors introduced by the rejection of figures beyond the rth place, adding one unit to the figure in that place when the first rejected figure is 5 or over, are distributed according to the first special law, p. 129. Thus the average error will be $\frac{1}{4}$ of a unit in the rth place at each rejection. These errors in a process of several additions or subtractions will accumulate as expressed by XIV., and by the special law of error just referred to. By these jointly it appears, then, that the accumulated error will be proportional approximately to $\sqrt{n}$ where n is the number of rejections. In multiplication or division the accumulation will follow the law of XVI., and XVII. At each step and in the final result the effect of each rejection will remain as the same fractional error of the quantity, though changing in its value in units in the rth place, in consequence of previous multiplications, etc. Thus in the final result the rejection errors as units in the rth place will follow the same law of distribution as at the point where they were rejected, and their combined effect may be computed as approximately proportional to $\sqrt{n}$, as for addition or subtraction. All other arithmetical processes may be regarded as combinations or modifications of the four primary ones. Let us then write as the limit $\frac{1}{4}\ \sqrt{n} < 1$ unit in the rth place, which solved for n gives $n < 16$. If, then, we reject always all places beyond the rth, we shall, on the average, not have in 16 rejections, and hence in any ordinary work, an accumulated computation error beyond the assigned small limit. We have, then, the following rules :—

Rules for significant figures :—1. In the δ ($a\,d$ or $A\,D$) two places of significant figures should in general be retained but the first place will sometimes suffice if the digit in that place is large.

2. In a single observation the last place of significant figures retained should be usually the rth place; viz., that corresponding to the second place of significant figures in the $a\,d$ of a series of such observations. It is sometimes sufficient to retain one place less than this when the digit in the first place of the $a\,d$ is large. In other words, retain the place corresponding to the last place properly retained in the $a\,d$ under rule 1.

3. In a mean or average, retain places to include that corresponding to the second place of significant figures of its $A\,D$. Sometimes one less place than this may suffice. In other words, retain places to correspond to the last place properly retained in the $A\,D$ under rule 1.

4. In addition or subtraction, carry the sum or difference only to that place which corresponds to the second significant figure in the $a\,d$ or $A\,D$ of the *least* precise quantity; *i. e.*, of the one with the largest δ. It will depend on the number and kind of quantities to be added or subtracted whether or not these quantities should each be carried to one place beyond that in which the last figure of the final result is desired, this extra place being rejected in the final result.

5. In multiplication (or division) carry out the product (or quotient) at any stage of the work only to the number of places retained in the original quantity under rule 2 or 3. If several measured quantities are to be multiplied (or divided) into each other, carry the product (or quotient) and the separate factors only to that number of places which would be retained under rule 2 or 3 in the least precise factor. It may sometimes be well to carry known factors, such as π, g, etc., to one place more than this rule would prescribe for the measured factors.

6. In the use of logarithms, the mantissæ should be retained to as many places as there should be places of significant figures retained, under rule 5, in the number corresponding, if the multiplication or division were to be performed directly. The characteristic is not to be considered, as it serves merely to locate the decimal point.

Closeness of corrections, constants, etc. Let M_1 be the mean of a series of observations, and δ_1 be its precision measure as computed from these. Let c be a correction to be added to M_1, and determined by comparison with standard, or in any way whatever, with a computed or estimated precision measure δ_c. Then δ, the precision measure of the corrected mean $M_1 + c$, will, by XIV., be found from $\delta^2 = \delta_1^2 + \delta_c^2$. Now, as already stated, it is obvious that anything producing on M_1 an effect less than about $0.1\ \delta_1$ may be considered as insensible or negligible. Keeping this in view we may obviously have the following cases :—

1. If $c < 0.1\ \delta_1$ the correction may be omitted.

2. If c is of the same order of magnitude as δ_1 it may be neglected only in coarse work, and should be then taken

into account in making up δ. As c, in any case, is of constant sign, this omission is not admissible in fine work.

3. Whatever the value of c, if $\delta_c < 0.1\,\delta$, then $\delta = \delta^1$ sensibly; so that c may be regarded as exact, and δ_c neglected.

4. Whatever the value of c, if $\delta_c > 0.1\,\delta$, then δ_c must be taken into account in making up δ.

Inspection will show that for constants, or other terms added to or multiplied into any quantity, such as M_1 above, the effect on M_1 of rejection of superfluous places of figures, or of errors or deviations in these quantities, may similarly be neglected when less than $0.1\,\delta_1$. Of course in very exact work this margin may be narrowed somewhat; in coarse work it may be broadened.

Estimated precision measures. Circumstances sometimes render it difficult or impossible to obtain the precision measure by direct observation. But in such cases it is often possible to obtain an approximate or estimated δ. A simple estimation of the $a\,d$ may be the best thing available. But usually it is easier to estimate what would be the extreme deviation which might occur in, say, 1,000 readings. Let h denote such an extreme deviation. Now, the general law of distribution shows that the deviation whose frequency is 1 in 1,000, has, in the long run, about four times the magnitude of the average deviation; *i. e.*, $h = 4\,a\,d$, whence an approximate $a\,d$ may be computed from an estimated h. This relation between h and $a\,d$ is often of service in other ways, as for instance where an extreme variation of some kind can readily be observed, but the average cannot.

Example. The following illustrates the application of the foregoing methods: Required the work W done in one stroke by an engine piston of diameter d and stroke s, working at a mean indicated pressure of intensity p as found from an indicator card. $W = \frac{1}{4}\,\pi\,d^2 ps$.

There may be two cases: one in which the data are already determined, and the quality of the result is under scrutiny; the other in which (as should always be done when possible) it is desired to determine in advance of the work what the precision should be in the components.

1. Having given the data and their precision measures, to find what reliance may be placed upon the result. In order to estimate the accuracy of the result, it is essential to inquire first into the accuracy with which the instruments were known, and whether they were properly applied in the measurements. Unless we can obtain suitable information on these points, which properly should go with the original statement of the result, it is impossible to discuss the quality of the result. Suppose, then, that it were further stated that the micrometric apparatus used in measuring the diameter and length of stroke had been tested under proper conditions, and corrections had been determined which brought its indications to agreement with the standard with an $a\,d$ of 0.00030 inch; also that the indicator spring had been checked against a mercury column, and the correction determined to an AD of 0.06 lbs.; also that due care as to temperature effects and all other discoverable sources of error was exercised when the measurements were made, so that it was deemed that no determinate source of error beyond the suitable limits was overlooked.

The data are:—

$d = 10.020$ in $\quad a\,d. = 0.010$ in. $\quad n. = 25. \quad \therefore A\,D. = 0.0020$ in.

$p = 20.00$ lbs. $\quad a\,d = 0.6$ lbs. $\quad n = 10. \quad \therefore A\,D = 0.20$ lbs

$s = 15.04$ in. $\quad a\,d = 0.0040$ in. $\quad n = 1.$

whence $W = 23720.$ inch-lbs.

We have now to find from the observed deviations their combined effect on the result. This is most readily done by separating into the factors $\frac{1}{4} \times \pi \times d^2 \times p \times s$. Of these, $\frac{1}{4}$ is an exact number; and π is a numerical constant known with indefinitely great closeness; so that both of these may be considered by themselves later, and carried to so many places as not sensibly to vitiate the result. Then by XX.

$$\left(\frac{\Delta W}{W}\right)^2 = \left(\frac{\delta\,d^2}{d^2}\right)^2 + \left(\frac{p}{p}\right)^2 + \left(\frac{\delta\,s}{s}\right)^2$$

From XVIII we have $\frac{\delta\,d^2}{d^2} = \frac{2\,\delta\,d}{d}$. Note that we cannot separate into the factors $\frac{1}{4} \times \pi \times d \times d \times p \times s$, because the third and fourth would then *not* be independent. Substituting, then, the numerical values $\delta\,d = 0.0020$ in., $\delta\,p = 0.20$ lbs., $\delta\,s = 0.0040$ in., we have

$$\left(\frac{\Delta W}{W}\right)^2 = \left(2.\frac{0.0020}{10.}\right)^2 + \left(\frac{0.20}{20.}\right) + \left(\frac{0.0040}{15.}\right)^2$$

$$= 0.00\,000\,016 + 0.00\,010 + 0.00\,000\,007 = 0.00\,010$$

$\therefore \frac{\Delta W}{W} = 0.010$ or 1 per cent., and $\Delta W = 0.010 \times 23720. = 240$ inch-pounds.

The number of places to be retained in π is such that the error introduced by the rejected places will not exceed 0.1 to 0.01 of the effect of the δ of the least precise factor in the data, viz., p. Now $\frac{\delta\,p}{p} = 0.0.010$. As π is a factor we have, then, $\frac{\delta\,\pi}{\pi} < 0.1 \times 0.010 < 0.0010$, whence $\delta\,\pi < 0.0010\,\pi < 0.0031$. Hence $\pi = 3.142$ will be exact enough. A better illustration of this point occurs in the second part of this example.

From this result for $\Delta\ W$ we know that the $a\,d$ of W is 240 inch-pounds, and that $\frac{a\,d}{W} = 0.01$, or 1 per cent. And as it has been shown that due regard has been paid to keeping the determinate errors suitably below the deviations, we are justified in using this value of $\Delta\ W$ as our estimate of the reliability of the result, as it is the best estimate which we can form. That is, other measurements made with a corresponding grade of care, but with wholly different instruments, would *probably* give results agreeing with this *on the average* to about one per cent. Unsuspected errors may, of course, exist, and of a nature not to be eliminated by averaging—whence the word "*probably*." For instance, it might have occurred that the indicator spring had received an unsuspected injury subsequent to test.

From the numerical values in the above expression for $\left(\frac{\Delta\ W}{W}\right)^2$, it will be seen at a glance that the precision in p is much too small as compared to that in d and s. Hence much of the labor spent in measuring the latter was thrown away. This might have been prevented, and the needful care might have been determined beforehand by the solution to be now given.

2. Required to determine in advance of the measurements, and from rough values, the necessary precision in the various components. The problem would be stated thus:—

Desired the work, W, done upon the piston of a steam engine in a single stroke under the indicated pressure p of about 20 pounds, the stroke s being about 15 inches, and the diameter d about 10 inches. Accuracy wished for in W is 1 in 1,000., or 0.1 per cent. How closely must the values of d, s, and p be measured, and how far should π be carried out?

Separate into factors the expression of W, as before, and lay aside the constants $\frac{1}{4}$ and π. Then imposing the condition of equal effects of the δ's upon the result, we have

$$2\,\frac{\delta\,d}{d} = \frac{\delta\,p}{p} = \frac{\delta\,s}{s} = \frac{1}{\sqrt{3}}.\ \frac{\Delta\ W}{W} = \frac{1}{\sqrt{3}} \times 0.001 =$$

0.00058

$\therefore\ \delta d = \frac{1}{2} \times 0.00058 \times 10. = 0.003$ inch.
$\therefore\ \delta p = 0.00058 \times 20. = 0.012$ pounds.
$\therefore\ \delta s = 0.00058 \times 15. = 0.009$ inch.

For the constant π we should have the requirement that $\frac{\delta \pi}{\pi} < 0.01 \times 0.00058 < 0.00006 \therefore \delta \pi = 0.00006 \times 3.1 = 0.00019$; whence $\pi = 3.1416$ would amply suffice.

It thus appears that for the assigned limit of accuracy $\frac{\Delta W}{W} = 0.001$, we must have the average deviations of d, p, and s respectively not over 0.003 inch, 0.012 pounds, 0.009 inch; and all determinate errors must have been so far removed from the work, by corrections and otherwise, that their residuals may safely be classed among the indeterminate errors. These δ's must include the average deviations not only of the direct measurements in each case, but those of the corrections used also, as stated in the paragraph on closeness of corrections.

(*To be continued.*)

ON THE PROPER SHAPE FOR ARMATURE CORES IN DYNAMO-ELECTRIC MACHINES.[1]

BY W. L. HOOPER.

It is now conceded that the wire upon the sides and inner surface of a Gramme ring and upon the ends of a drum is idle; only the conductors upon the face of an armature being actively engaged in the generation of electromotive force. Accordingly, the drum has been made long that the largest possible amount of wire might lie upon its face; and the wire upon the inner surface of a Gramme armature has been made active by the employment of auxiliary poles placed within the ring. But has the activity of the whole armature wire been thereby increased? At first sight it would appear that of two armatures having the same length of wire, that having the greatest length actively employed in cutting lines of force would generate the highest electromotive force. But let us look at an actual case. Suppose a Gramme ring having a core two inches square and provided with both external and internal poles. Let the magnetization of the core be just below saturation, this condition being acquired by the passage of n lines of force. There is a half revolution, of the eight inches of wire in a single turn; two inches on the face of the armature will cut $2n$ lines and the two inches on the inside wire cut the same number, making n lines of force cut by a single turn of wire, half of which is active. Now it is well known that it is perfectly easy to saturate the core of a Gramme ring without internal poles; in which case there are n lines of force cut by a single turn as before; though they are now cut by the two inches on the face of the ring. It is thus seen that the electromotive force depends solely upon the number of lines of force cut by a turn of wire, not at all upon what fraction of the length of that turn may be active. Furthermore, since it is well known that internal poles tend greatly to increase magnetic leakage, it is quite certain that the magnetization of the cores will be obtained with the least expenditure of energy in the field magnets when only external poles are employed.

The drum or cylinder armature is sometimes made several diameters in length. Let us compare such an armature two feet long and six inches in diameter with one a foot long and a foot in diameter. Both will have a magnetic cross-section of one square foot; moreover, they will present about equal surfaces to the pole-pieces. A single turn of wire in either will cut $4n$ lines of force in a complete revolution; but while the long armature contains only half the length of dead wire, it contains 25 per cent. more wire in all, and yields the same electromotive force. Moreover, to get the same strength of field in the machine with the long armature, much more wire will be used and electrical energy expended.

Theory then demands that for any armature there shall be the greatest possible cross-section of iron with the least possible length of wire. This indicates a circular cross-section for the iron core of a Gramme ring and a spherical form for the Siemens armature. I think it probable, however, that mechanical considerations favor a flat faced armature; but in obtaining this the conditions above imposed should be departed from as little as possible.

ON DYNAMOMETERS.

BY HEFNER ALTENECK.

Translated from the *Electrotechnische Zeitschrift*, December 1887, for the ELECTRICAL ENGINEER, by J. HOWARD PRATT, Jr.

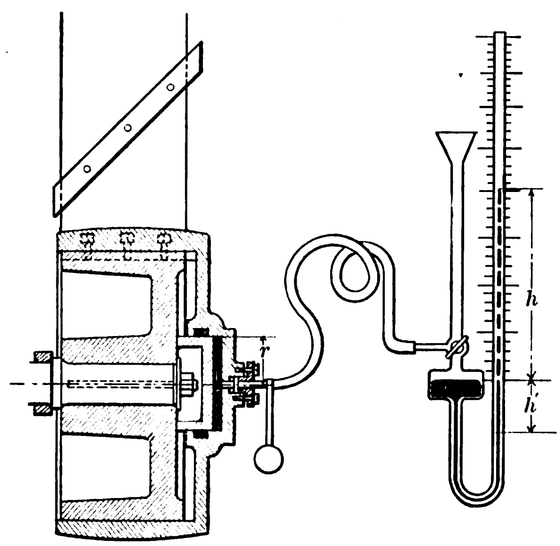
I INTEND in the following article to bring to your notice a new contrivance which is intended to serve for the determination of force, and which is used at the works of Siemens and Halske for testing dynamo-electric machines. The characteristic feature of this consists in bringing to equilibrium by hydraulic means the force to be measured.

About two weeks ago, Mr O. H. Müller, of Charlottenburg sent to me, for my opinion, designs of a registering dynamometer, which though different in its details of construction, nevertheless was devised upon a practically similar principle. This prompts me to delay no longer the publication of the older machine which was invented in March of this year [1887], and to my knowledge is the first dynamometer with hydraulic transmission.

I may, perhaps, assume it as known that, not only at the works of Siemens and Halske, but, following our precedent, at several other places also, force is measured in belting by means of an apparatus in which both parts of the belt, the actuated and the actuating, are strained equally and symmetrically from their direct tension by a pair of pulleys joined together or by one pulley laid between them. The force with which the pair of pulleys or the single pulley tends to be deflected to one side of its middle position is proportional to the difference in tension of the belts, *i. e.*, to the force to be measured. This is determined by means of a spring balance attached to the instrument. The older form of this dynamometer, namely that with the two movable pulleys, furnishes more accurate results, but requires for every time it is used a separate careful adjustment and measurement of the sag of the belts. Therefore, the other form of apparatus, which has only one movable pulley and besides that only a little gearing, and which requires no accurate adjustment, has come into more general use. While it can be regarded an advantage of this dynamometer in comparison with other systems that all pulleys run with relatively very slight pressure and, therefore, the friction of their bearings and other resistance to motion are comparatively very small, still the measurements by this method may, under unfavorable circumstances, prove a few per cent. too high. For most cases, and especially for the practical needs of measurement of forces in dynamo-electric machines, the degree of accuracy attained is still abundantly sufficient; however, for theoretical investigations, particularly in the case of electrical transmission of energy, it is valuable to have an equally simple and yet more accurate method. The hydraulic dynamometer, a design of which in cross-section is given in the accompanying cut, is intended to serve this purpose.

The main feature of the apparatus consists merely in a modification of the actuated pulley which still retains its exterior diameter.

The rim of this pulley only loosely surrounds the inner core, which, as usual, is fastened to the shafting, and is faced cylindrically on the outside. The mechanical union of the two parts is effected at their surface of contact by four equally separated so-called "tongue and grooves." These are arranged, not as usual and as is represented in the cut for the sake of greater clearness, in a direction parallel to the axis, but in a helix inclined 45° to it. The core of the pulley, accordingly, forms a screw of several threads with steep pitch and large diameter, the rim forming the female screw. The consequence of this is that every force of rotation which acts upon the circumference of the pulley tends at the same time to move the rim of the pulley tangentially upon the core in the direction of the axis. The direction of the screw is so chosen with reference to the direction of revolution of the pulley, that this displacement occurs towards the instrument. The rim of the pulley is closed in front by a partition which covers the face of the core. In the middle of this



partition on the side towards the core is found a cylindrical hole, in which is fitted a plunger that rests against the face of the core. The fitting is done in the old approved way, as in the hydraulic press, by circular washers. The space between the plunger and the front partition communicates by a small hollow cylinder and rubber tubing with an ordinary mercury manometer. The cylinder is conducted from without through packing, and outside is kept in some way from revolving. The space between the plunger and the partition, the cylinder, and the tubing, including the space over the mercury surface, are filled with a light fluid (preferably glycerine), for which a funnel, a three-way cock and, in the hollow space, an air vent that can be closed, are conveniently arranged.

From all this it is clear that the force of rotation of the belt is transmitted to the fluid enclosed between the plunger and the outer partition, with a total stress equal to that which it exerts on the radius of the thread of the screw at 45° inclination. In consequence of this, the enclosed fluid exerts in all directions, according to the well-known hydraulic law; upon each unit of surface, a pressure equal to the pressure on the plunger divided by the surface of the plunger. Just as in the hydraulic press from a small plunger to a large one, only by a reverse process, this pressure is transmitted to the mercury manometer, and is indicated there by the height of the mercury column, which is read on a long scale.

Neglecting the corrections mentioned below, the height of the mercury is proportional to the force to be measured.

It might be supposed that in the method described for mechanical transmission, friction on the thread of the screw and the plunger would prevent accuracy. Here, however, was again absolutely confirmed an observation which I had already had frequent opportunity to make, namely, that friction in well adjusted apparatus is never troublesome if all the parts are in motion or are under the influence of vibrations. Although the friction between the rim and the core of the pulley at rest is very great, because the entire strain of the tension of both belts is here exerted, nevertheless its injurious effect disappears entirely if the pulley is revolved.

The height of the mercury column changes up and down about a millimeter for every slight variation in the force to be measured, by which the proof that it is permanently influenced by no kind of friction is practically established.

On the other hand, the influence which the centrifugal force of the fluid rotating with the pulley exerts on the manometer, at least when the number of revolutions is great, must not be neglected. This, however, can be reckoned and the necessary correction can be obtained from a table. It is known that the surface of a fluid rotating in a circular vessel is heaped up at the edge, and, on the whole, assumes the form of a paraboloid. So, on being rotated, the enclosed fluid, in consequence of centrifugal force, exercises, not only against the periphery but also against the lateral faces, a pressure which is greatest at the circumference and nil at the centre. Suppose first the centrifugal force acting alone, a total pressure will be felt against the front partition of the fluid receptacle, which is equal to the sum of all the pressures against it, provided only that it cannot yield to this pressure. Because, however, this goes on without interruption as long as liquid can flow in at the centre, an expression for the entire pressure is obtained in that for every element of surface, a pressure which is equal to the mean value of the total centrifugal pressure, is introduced as a negative factor. This mean negative pressure, (according to the principle that the volume of a paraboloid is equal to half the volume of the circumscribing cylinder), is equal to half the maximum pressure exerted at the circumference. In the middle, where the cylindrical tube opens and there is no centrifugal force, this pressure reaches its full value and exerts a retarding action, which diminishes the height of the mercury in the manometer tube.

To determine the constants of the instrument the following method is best. First of all, one cannot be sure that the inclination of the thread really amounts to 45°; or, rather, one must determine on which radius that is the case. As is known, the inclination of an ideal screw-surface decreases in proportion to the radius on which it is measured. So, after taking away the rim, draw on the circumference of the core a straight line parallel to the axis. Restore the rim and revolve it any distance on the core. Measure not only the magnitude of this revolution in the displacement of the circumference of the inner surface of the rim with reference to the line that was drawn, *i. e.*, the corresponding length b, of the radius of the plunger, R, but also the simultaneous displacement a, on the line drawn. Now let R be that radius on which the inclination of the thread is as 1:1 (*i. e.*, 45°), then

$$R = \frac{a}{b} R^1.$$

The force acting on radius R, is transmitted to the plunger in this ratio.

Moreover, let

r = radius of plunger in meters,
h = difference in level of the two mercury surfaces in the manometer.
h^1 = (in centimeters) the height of the mercury column due to centrifugal force.
S = specific gravity of the enclosed fluid (for glycerine = 1.26).
n = number of revolutions per minute.
P = the force acting on the radius R (where the inclination of the screw is 45°) = the pressure on the plunger.
N = the horse-power transmitted through the pulley.

Then

$h^1 = 0.00206\ n^2\ r^8\ s.$

$P = 425.6\ r^2\ (h + h^1).$

$N = 0.594\ R\ r^2\ n\ (h + 0.00\ 206\ n^2\ r^2\ s).$

R and r, taken in meters, h and h^1 in centimeters, specific gravity of mercury, 13.55.

It is seen from these formulæ that it is only necessary to take r sufficiently small to make the $h+h'$ corresponding to a force P, appear as large as you please. There is no objection to making the scale of the manometer a meter or more in length, by which is secured an extraordinarily distinct reading and sensitiveness of the indicator. The damping of oscillations, essential in all such apparatus and often so difficult to secure, is, notwithstanding, perfectly attained in consequence of the friction of the liquid in the tubes, which, by merely turning the cock, can be regulated at will.

If the hydraulic dynamometer be compared with the belt-dynamometer, the latter has, to be sure, the advantage that its use requires no contrivance on the machine itself, and the same instrument, within its limits of work, can be used for every machine immediately. On the other hand, however, its use as a fixture for continual control of a machine is as good as excluded, because no one will burden himself with its permanent adjustment and maintenance, as well as its noisy action.

For just this purpose the hydraulic dynamometer is very useful, because it has no superfluous gearing and takes up almost no room, and, indeed, is scarcely noticeable in the outward appearance of the machinery. The scale can be fixed at any desired point (for example, the wall of the machine shop) and made visible at a distance. It is to be recommended for this case to arrange instead of the funnel a small force-pump, so that, if the fluid should in time be lost through some incompactness in the material, it can be continually replenished even during its action and without disturbing the measurement. The amount of enclosed fluid is immaterial for the measurement.

The hydraulic dynamometer can be employed for small as well as for infinitely great forces to a degree that is true in no other systems. With slight mechanical changes also it can be made self-registering for a projecting axle or put in connection with a clutch instead of a pulley. I believe, therefore, that it will do good service in many cases. At any rate, the practical engineer will easily be able to judge whether the new apparatus or the older belt-dynamometer is better adapted for an individual case.

I feel myself constrained still to add to the preceding communication a rejoinder to a circular which is published by the firm of Ganz & Co., in Buda-Pesth, and in which a belt-dynamometer constructed by that firm is recommended as preferable, while to the "well-known dynamometer of Von Hefner-Alteneck" is summarily ascribed an uncertainty and liability to error which would make it as good as useless for modern technique. The dynamometer described in the circular is constructed as a separate piece of apparatus, which makes necessary, in all, three separate belts. The middle one runs over four pulleys, each of which it half encircles—two stationary and two fitting on a common movable piece, which revolves about a fixed point with the force of the difference of tension of the belts. The working of this apparatus rests, then, on the same principle as the already-mentioned much older belt-dynamometer without special belts; yet with this distinction, that the index remains approximately correct for a greater deflection of the movable piece and can thus be used for registering. By a whole page of computations it is then shown that the limits of error of the instrument do not exceed $\frac{8}{1000}$ per cent.

It is, then, perfectly plain that from the similarity of the principle, almost the same calculation—its correctness being assumed—must also serve directly for the older instrument, condemned as inaccurate by Ganz & Co., and thus at least an equal accuracy be ascribed to it also. Unfortunately, however, the result of the computation as well as the conclusion drawn from it, that from an assumed zero-point the resistances of the apparatus are constant and therefore may be eliminated, is not borne out by the facts; for, in the single pulley over which the belt runs, the resistances of motion influencing the result are dependent not only on the transmitted power, but also on the initial tension.

There is, then, nothing left but to make the initial pressure which these resistances produce as small as possible. On more careful investigation, however, it is found that in the older instrument this injurious pressure enters to a far less extent than in that of Ganz, because not the full traction of the single parts of the belting, but only small components of them, which also partly neutralize each other, affect the pulleys. Just so, too, the further criticism raised, that in the older instrument, pivots instead of knife-edges are used, has no weight. According to the already related experience, by using the latter, which are exposed to violent vibrations, accuracy is in no case increased, while durability is lessened. The unfavorable opinion of the older instrument given by Ganz & Co. lacks, then, any foundation in fact.

THE MAXIMUM EFFICIENCY OF INCANDESCENT LAMPS.[1]

BY JOHN W. HOWELL.

THE word efficiency, when applied to an incandescent lamp, is used to designate the amount of energy required by the lamp for the production of a given amount of light; thus we say that a given lamp has an efficiency of three watts per candle, at 16 candles, meaning that to produce

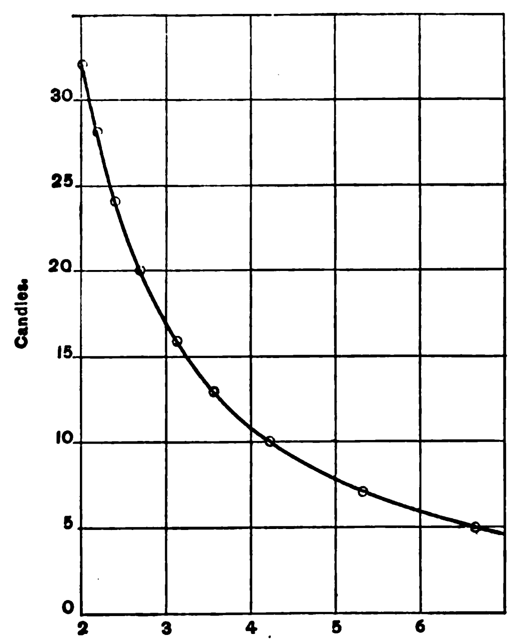


Fig. 1.

an illumination of 16 candles we must supply the lamp with 48 watts.

The word efficiency, when applied to a prime mover or to any piece of apparatus that changes energy from one form to another, or which transmits or utilizes energy, has a well defined meaning, and is used to represent the ratio of the energy of the useful effect produced by the apparatus, to the energy necessarily supplied to the apparatus to enable it to produce that effect.

An incandescent lamp transforms electrical energy into heat and light; so the use of the word efficiency to denote

1. A paper read before the American Institute of Electrical Engineers, April 10, 1888.

the watts per candle required by the lamp is not a proper one. To denote properly the efficiency of an incandescent lamp we must be able to separate the energy of the light produced by it from the energy of the heat produced. Then the ratio of the energy of the light to the electrical energy required by the lamp will be a correct expression for the efficiency of the lamp, and we will have to find

Curve showing lives of equally good lamps, burned at different efficiencies.

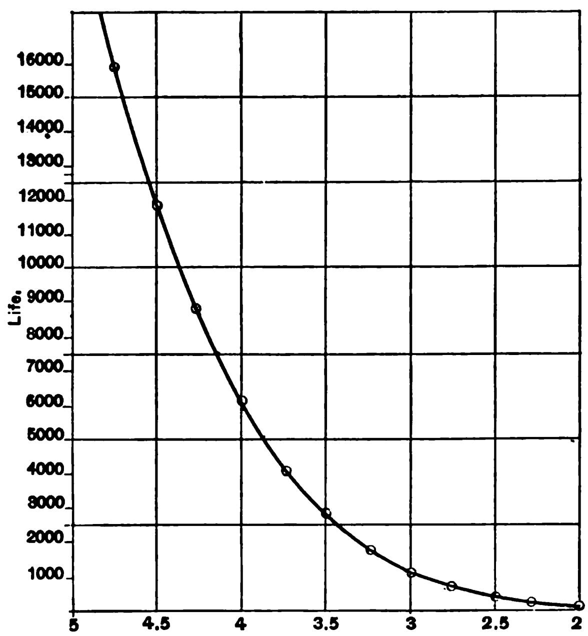

Fig. 2.

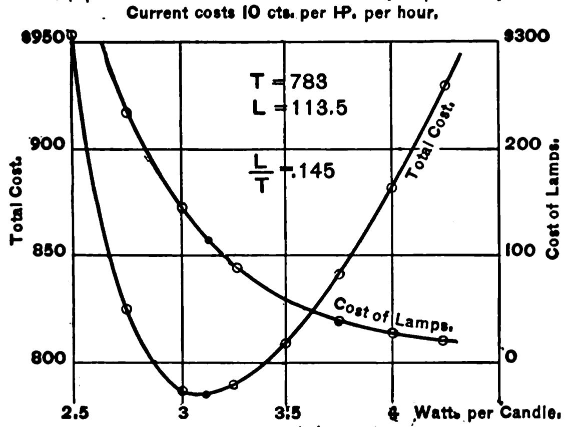
some other word to designate the watts per candle. In this paper the word efficiency is used in its ordinary improper sense to denote the watts per candle required by a lamp when producing a given amount of light.

Lamps 85 cts. each—Life 600 hrs. at 3 Watts per Candle. Current costs 10 cts. per HP. per hour.



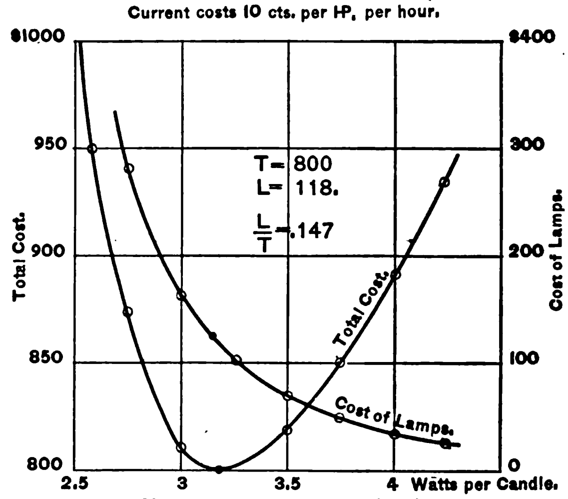
Minimum at 3.1 Watts per Candle.
∴ Maximum Efficiency 3.1 Watts per Candle.

Fig. 3.

The efficiency of a lamp varies with its candle-power. The curve, figure 1, shows the rate of this variation for a particular lamp. At five candles this lamp has an efficiency of 6.7 watts per candle; at 10 candles it is 4.2 watts per candle, and at 20 candles it is 2.66 watts per candle.

Any statement regarding the efficiency of a lamp must, therefore, be accompanied by a statement of the candle-power at which it has the stated efficiency; without this it is meaningless. There is nothing in an incandescent lamp itself that fixes its proper efficiency or in any way indicates what it is. The lamp from which the curve, figure 1, was determined has, within the limits of the curve, any efficiency between two and seven watts per candle. Thus, by simply changing the candle-power of the lamp, we can operate it at any efficiency we choose, and get as much or as little light per watt as we choose.

Lamps $1.00 each—Life 600 hrs. at 3 Watts per Candle. Current costs 10 cts. per HP. per hour.

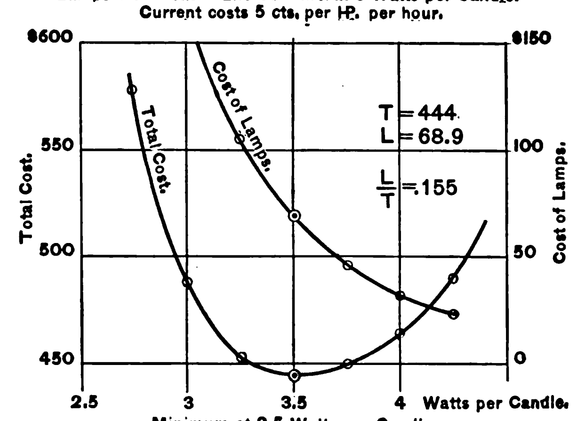


Minimum at 3.18 Watts per Candle.
∴ Maximum Efficiency 3.18 Watts per Candle.

Fig. 4.

In commercial practice the candle-power of lamps is always marked on them, and their efficiency at this candle-power is stated; but even this is not a proper index to the value of the lamp or to its proper efficiency. Experience has shown that lamps are almost universally run above their normal rating; lamps rated at 4.5 watts per candle are usually run at from 3.5 to 4 watts per candle, and in order to make lamps that will stand the strain of being run above their rated capacity, it is necessary to rate them considerably below the efficiency at which they will give the best results under ordinary circumstances.

Lamps $1.00 each—Life 600 hrs. at 3 Watts per Candle. Current costs 5 cts. per HP. per hour.



Minimum at 3.5 Watts per Candle.
∴ Maximum Efficiency 3.5 Watts per Candle.

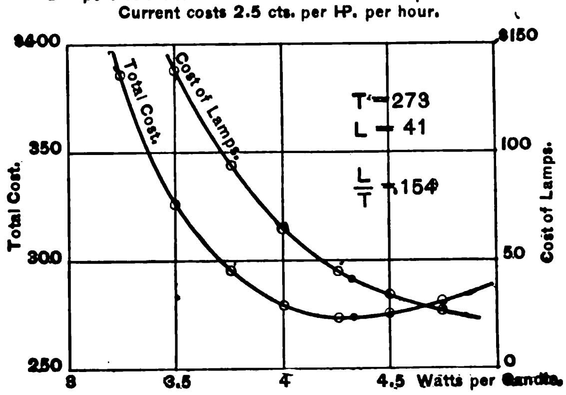
Fig. 5.

Lamps have been made and sold in England which have a very high rated efficiency, but parties buying these lamps are told that they will get very much more satisfactory results if they run the lamp *below their rated capacity.* So we see that some lamps are rated above their capacity and some are rated below, and the rated efficiency of a lamp is not always the best efficiency at which to run it. How, then, are we to determine the efficiency at which a lamp will give the best results? It is this question which I will attempt to answer.

The term "maximum efficiency" of a lamp, as used in the title of this paper, does not mean the highest efficiency at which a lamp can be operated, but the efficiency at which the best results are produced by the lamp: or more accurately, *the efficiency at which the cost of operating the lamp is a minimum.*

Taken in this latter sense, the maximum efficiency of a lamp is not its highest efficiency. As we increase the candle-power of a lamp its efficiency increases; consequently, by running the lamp high enough we can make its efficiency so high that very little power is required to produce a given amount of light and the cost of the power to produce the light is very small. But, while the efficiency of the lamp increases, its life decreases, and if we run a lamp at too high an efficiency, the saving in the cost of power is more than balanced by the increased cost of lamp renewals.

Lamps $1.00 each—Life 300 hrs. at 3 Watts per Candle.
Current costs 2.5 cts. per HP. per hour.

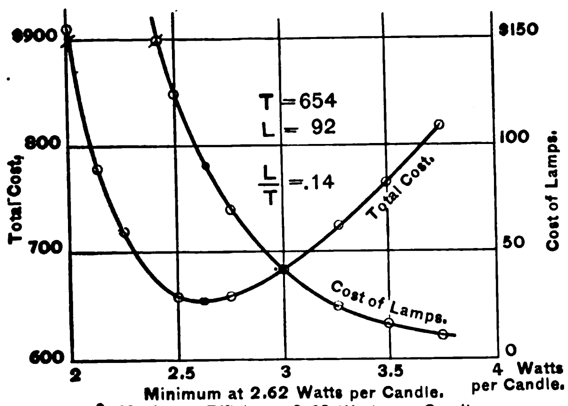


Minimum at 4.32 Watts per Candle.
Maximum Efficiency 4.32 Watts per Candle.

Fig. 6.

To determine the maximum efficiency for lamps under given conditions we must determine the efficiency at which the sum of the costs of power and lamps is a minimum, and in order to do this we must know the rate of variation of the life of a lamp with its efficiency.

Lamps 50 cts. each—Life 1200 hrs. at 3 Watts per Candle.
Current costs 10 cts. per HP. per hour.



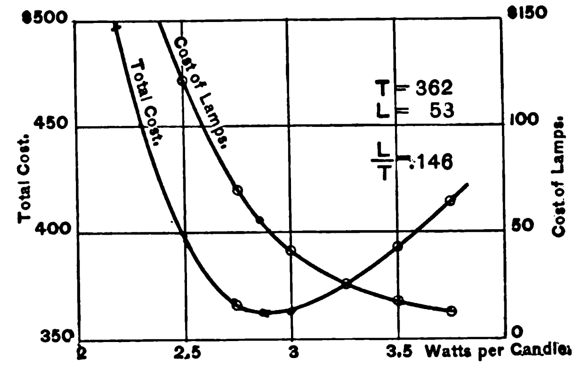
Minimum at 2.62 Watts per Candle.
Maximum Efficiency 2.62 Watts per Candle.

Fig. 7.

The curve, figure 2, shows this rate of variation. This curve is the result of very carefully conducted experiments made by the Edison company. These experiments extended over five years and consumed a very large number of lamps. Its accuracy when applied to Edison lamps is beyond question; but our experiments with lamps having an artificial surface on the carbon, or "flashed" lamps as they are called, show that their rate of variation of life and efficiency follows a different curve.

This curve does not apply to individual lamps. If we take two Edison lamps and burn them at different efficiencies, their lives for these efficiencies will probably not be such as indicated by the curve, nor will they be proportioned to these indicated lives. But if we take 100 lamps and burn them at one efficiency, and another hundred equally good lamps and burn them at another efficiency, the average lives of the two sets will be proportional to the lives indicated by the curve for these two efficiencies.

Lamps 50 cts. each—Life 1200 hrs. at 3 Watts per Candle.
Current costs 5 cts. per HP. per hour.

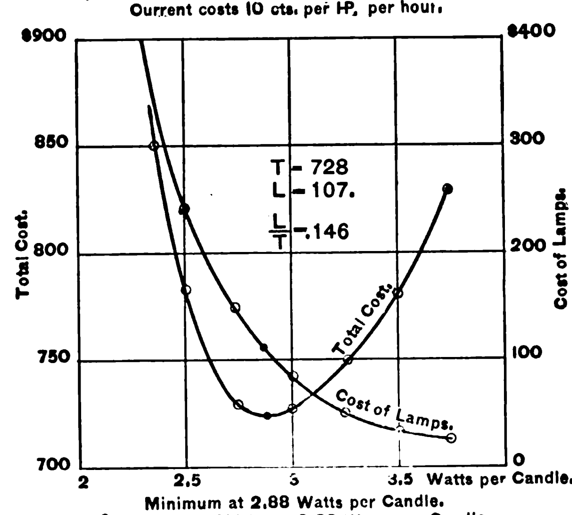


Minimum at 2.825 Watts per Candle.
Maximum Efficiency 2.88 Watts per Candle.

Fig. 8.

In order to determine at what efficiency the cost of operating lamps of a given quality under given conditions is a minimum we must calculate what this cost is at different efficiencies. To do this we consider the total cost of operating the lamps to be made up of two parts, viz., the cost of the *current* and the cost of the *lamps.* The cost of the current is made up of every expense incurred in operating the lamps, including materials consumed, labor, taxes, insurance, rent, and every other expense incurred in operating the plant, except the cost of lamps.

Lamps 50 cts. each—Life 600 hrs. at 3 Watts per Candle.
Current costs 10 cts. per HP. per hour.



Minimum at 2.88 Watts per Candle.
Maximum Efficiency 2.88 Watts per Candle.

Fig. 9.

The cost of the lamps is an item by itself, and is the amount which the lamp has cost when it is put in use. This is a natural division of the total cost of operating a plant, since to produce light by incandescence all that is necessary is a lamp and current to operate it.

If, in any case, we know the cost of the current required to operate the lamps, the cost of the lamps, the quality of the lamps,—that is, the life they will give when burned at a given efficiency,—and the rate of variation of their life with efficiency, we can then calculate at what efficiency the

cost of operating the lamps is a minimum, and this I call the maximum efficiency of those lamps.

The following examples show what this maximum efficiency is under varying conditions of the cost of lamps—the cost of current and the quality of the lamps. The cost of the lamps I have varied between 25 cents and $1.00 each. The cost of current varies between 2.5 cents and 10 cents per h. p. per hour. The quality of the lamps varies between 300 hours life at 3 watts per candle, and 2,400 hours life at 3 watts per candle.

In each of the following cases I have calculated the cost of operating 100 16 c. p. lamps 1,000 hours, at each of the efficiencies comprised in the curve of total cost. These curves do not show the cost of running the same lamps at different efficiencies, but the cost of running equally good 16 candle lamps of the different efficiencies.

The first case we will consider is shown in the diagram figure 3. In this case the lamps are assumed to cost 85 cents each, and to have a life of 600 hours at 3 watts per candle. The current is assumed to cost 10 cents per h. p. per hour.

The cost of the current is determined from the following formula :—

$$\text{Current cost} = \frac{\text{w. p. c.} \times 16 \times 100 \times 1{,}000 \times \text{cost of ct. per h. p. per hour}}{746}$$

And the cost of lamp from this formula :—

$$\text{Cost of lamps} = \frac{\text{cost of one lamp} \times 100 \times 1{,}000.}{\text{Life at given efficiency}}$$

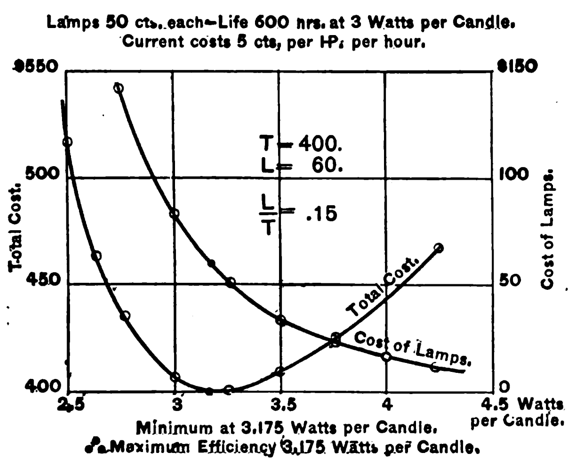


Fig. 10.

The curve marked *total cost* shows the total cost of running 100 10 c. p. lamps 1,000 hours, the efficiencies of the lamps varying between 2.5 and 4.25 watts per candle. The efficiencies are shown by the vertical lines, referring to the scale at bottom. The value of the total cost at any point of the curve is shown by the horizontal line through the point, referring to the scale at the left of the diagram.

The lowest point of the curve shows the point where the total cost is lowest. This is the minimum cost of operating these lamps under the given conditions. The mark at the lowest point of the curve shows this minimum cost to be $783, and a vertical line through this point to the scale at bottom of the diagram shows that this total cost is a minimum when lamps having an efficiency of 3.1 watts per candle are used.

Thus the maximum efficiency of these lamps under the conditions assumed is 3.1 watts per candle.

The lamps considered in the case, shown in figure 4, cost $1.00 ; all other conditions are the same as in the case shown in figure 3. This increases the total cost from $783 to $800, and necessitates using lamps of 3.18 watts per candle instead of 3.1, to make the cost of operating a minimum.

In the case shown in the diagram, figure 5, the current costs 5 cents per h. p. hour ; the other conditions are the same as in the case assumed in figure 4. The minimum total cost in this case is $444, and to make this cost a minimum we must use lamps having an efficiency of 3.5 watts per candle.

In this case, shown in figure 6, the lamps cost the same as in the last, but are only half as good ; the current costs just half as much as in the last case. The minimum total cost in this case is $273, and the maximum efficiency of the lamps is 4.32 watts per candle.

In the case shown in figure 7, the lamps cost 50 cents and have a life of 1,200 hours at 3 watts per candle. The current costs 10 cents per h. p. per hour. This is the cheapest and also the best lamp we have yet considered, but the current is expensive. In this case the minimum total cost is $654 and the maximum efficiency of the lamps is 2.62 watts per candle. In this case, figure 8, the current costs half as much as in the previous case, other conditions being the same. The minimum total cost is reduced from $654 to $362. The maximum efficiency in this case is 2.88 watts per candle. In figure 9, the current costs twice as much as in the previous case, and the lamps are only half as good. The minimum total cost is doubled, but the maximum efficiency is the same as in the previous case.

In this case, figure 10, the current costs one-half of that assumed in the previous case, other conditions being the

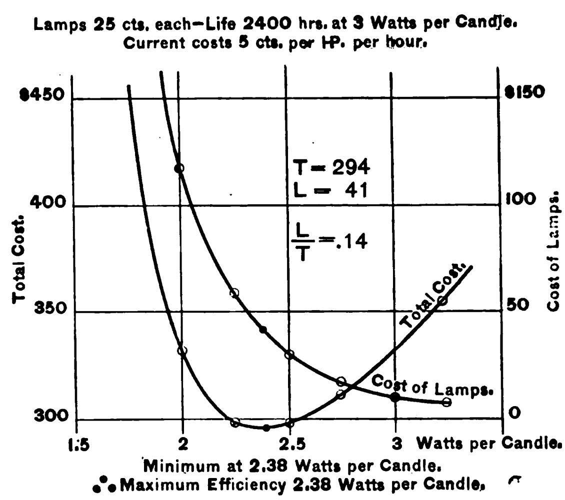

Fig. 11.

same. The minimum total cost is $400, and the maximum efficiency is 3.175 watts per candle.

The curve, figure 11, illustrates the case of very cheap and very good lamps, with moderate cost of current. The minimum total cost is low, $294, while the lamps are run at the high efficiency of 2.38 watts per candle.

In the case shown in figure 12, the cost and quality of the lamps are the same as in the previous case, but the current costs twice as much. This increases the minimum total cost from $294 to $535, and raises the maximum efficiency to 2.14 watts per candle.

In the case, figure 13, the cost of lamps and the cost of current are the same as in the case shown in figure 11, but the lamps are only half as good. The minimum total cost is increased from $294 to $327 and the maximum efficiency is reduced from 2.38 to 2.62 watts per candle.

The first and plainest inference drawn from these curves is that the maximum efficiency of any given lamp is not a fixed one, but varies with conditions outside the lamp itself. Identical lamps operated under different conditions of cost of current must be burned at different efficiencies to make the cost of operation a minimum for the production of a given amount of light. In order to determine the maximum efficiency of lamps, therefore, we must know the quality of

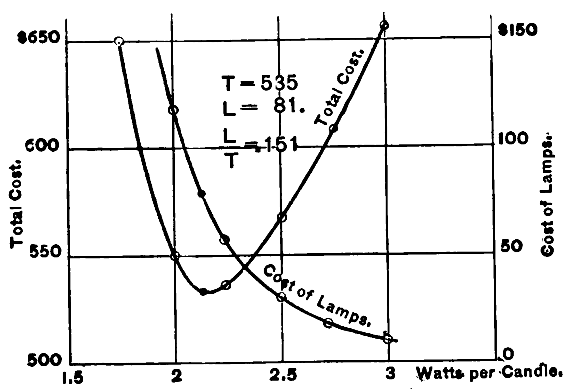
the lamps referred to some standard, the cost of the lamps to the consumer, and the cost of current under the actual conditions existing at the place where the lamps are to be used

In the eleven cases shown in this paper the lamp of highest efficiency is obtained in the case shown in figure 12. This is a case where the lamps are very cheap and very good, and current is very expensive. The lamp having the lowest efficiency is obtained in the case shown in figure 6, in which the lamps are poor and high-priced and the current is very cheap.

There is a marked difference in the sharpness of these curves at the minimum points. An inspection will show that the sharpness of the bend in these curves depends upon the cost of the current, the curves in which the current costs 10 cents per h. p. per hour being the sharpest. Those in which the current costs 5 cents are next, and the one, figure 6, in which the current costs only 2½ cents per h. p. per hour, is very flat at the bottom or minimum point. In this comparison figure 7 is not considered, as it is drawn on a different scale from the others, and is not as sharp as it should be.

This indicates that the more expensive the power is, the more carefully must the lamp efficiencies be chosen. In figure 12, which shows the sharpest curve, a very slight variation in the efficiencies of the lamps makes a very great change in the total cost of operation.

Lamps 25 cts. each—Life 2400 hrs. at 3 Watts per Candle.
Current costs 10 cts. per HP. per hour.



Minimum at 2.14 Watts per Candle.
⁂ Maximum Efficiency 2.14 Watts per Candle.

Fig. 12.

In the case shown in figure 6, in which the current is very cheap, we find that a very considerable change in the efficiency of the lamps used makes very little difference in the total cost of operation.

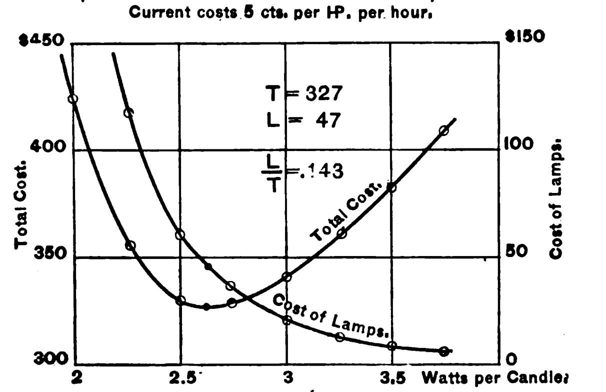
On each of the eleven plates two curves are drawn, one showing the total cost of operation, and the other showing the cost of lamps. On each of the curves showing the cost of lamps a point is marked which indicates the cost of the lamps when the total cost is a minimum. The letter T marked on each of the figures denotes the minimum total cost of operating the lamps under the given conditions. The letter L denotes the cost of the lamps when the total cost is a minimum; and the expression $\frac{L}{T}$ denotes the ratio of the cost of lamps when the total cost is a minimum, to the minimum total cost. An examination of all these curves shows that while the minimum total cost varies with each of the three quantities—price of lamps, quality of lamps and cost of current—nevertheless, *the total cost is always a minimum when the cost of lamps is about* 14.5 *or* 15 *per cent. of the total cost of operation.*

This figure varies somewhat in the different examples considered, but the variation seems to follow no law. In figures 6 and 12 which show the highest and lowest efficiency lamps the figures are 15.1 per cent. and 15.4 per cent. respectively.

The steepness of the curve showing the cost of lamps, and the difficulty of determining the exact minimum point of a curve which has been drawn by inaccurate methods makes it difficult to get the cost of lamps accurately when total cost is a minimum. These curves and values are given just as they were determined, and no effort has been made to bring the results into closer agreement, as could readily have been done. I consider the variation shown by these curves to indicate closely enough that this ratio of cost of lamps to total cost at the minimum point is nearly, if not quite, constant, and that its value is between .145 and .15.

This establishes a very simple law for determining whether or not lamps are being operated at their maximum efficiency; for if they are, the lamp bills will be about 15 per cent. of the total operating expenses of the plant. If the lamp bills are more than 15 per cent. of the total operating expenses the lamps are being burned above their maximum efficiency, and lower efficiency lamps should be obtained. If, on the other hand, the lamp bills are less than 15 per cent. of the total expenses of the plant the lamps are being burned below their maximum efficiency, and higher efficiency lamps would reduce the cost of operating the plant. Where fuel is high priced, or where other causes operate to make the cost of generating current high, it is specially important to use lamps of the maximum efficiency; for we have seen from the above curves that where the cost of current is high the use of lamps whose

Lamps 25 cts. each—Life 1200 hrs. at 3 Watts per Candle.
Current costs 5 cts. per HP. per hour.



Minimum at 2.62 Watts per Candle.
⁂ Maximum Efficiency 2.62 Watts per Candle.

Fig. 13.

efficiency is a little above or below the maximum efficiency attainable under the conditions of operation, makes a very marked increase in the operating expenses of the plant.

If in any plant the lamp bills are only 10 per cent. of the total expenses, then *increasing the efficiency of the lamps by increasing their candle-power does not diminish the total cost of operating the plant.* In order to reduce the total cost *the lamps must be replaced by lamps of the same candle-power but of higher efficiency.* If the efficiency of the lamps is increased by raising their candle-power, the cost of operating the plant *per unit of light produced* is reduced, but the total cost is increased. A plant which is paying less than 15 per cent. of its total expenses for lamps, and which brings the lamp bills up to 15 per cent. by increasing the candle-power of the lamps does not decrease the cost per lamp of operating the plant but *does* decrease the cost per candle of light furnished. If they are paid for the increased light given by the lamps the efficiency of the plant is made a maximum for the existing conditions; but if they are not paid for the additional light furnished the efficiency of the plant is reduced.

This law enables any one operating an incandescent lamp plant to determine whether or not he is using the most suitable lamps for his plant. If the conditions of operation of a new plant are all known, and the quality of the lamps made by any lamp maker is known, we can determine before starting what is the most economical lamp to use.

THE DEVELOPMENT OF THE MERCURIAL AIR PUMP.[1]

BY PROFESSOR SILVANUS P. THOMPSON, D. SC., B. A.

(Continued from page 175.)

THE Toepler form of pump has received in recent years various modifications. E. Wiedemann[2] altered the overhead tube, H, by joining it at its base with two of Gimingham's air-tight joints, allowing it to be removed to be cleaned. Neesen[3] added the side-tube shown at N, in figures 18 and 33, to prevent the top of the pump-

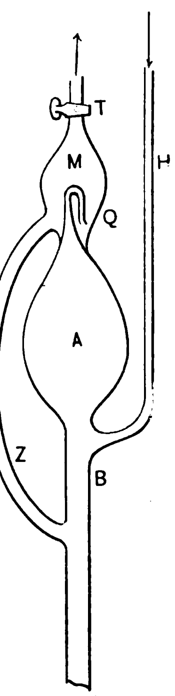


Fig. 29.

Siemens's Pump. (First Form.)

head being broken off by violent uprushes of mercury in the large bulb. Guglielmo[4] ingeniously connected the closed top of the collecting vessel (into which the exit tube discharged air and mercury) with the closed top of the supply vessel, so that as the latter was raised, and the mercury ran out of it, the air-pressure upon the lower end of the barometric column in F was automatically lessened. Improved forms of overhead tube were suggested by von Helmholtz[5] and by Schuller,[6] and a very similar device was used by the writer in 1882 to connect a glow lamp to the Lane-Fox pump by merely sealing it to the top of a long barometric tube, which slipped on over the top of the open overhead tube—or of a tube connected with it—and dipped into an external ring of mercury in a cup forming a barometric air-tight trap. Neesen[7] designed a double-acting pump on this plan, with two pump-heads, and two fall-tubes, the mercury being mechanically driven alternately from one pump to the other by a piston working in a cylinder. The model has not yet been actually constructed.

Other improvements have been made in detail by Couttolene,[8] who drives the air into a partially exhausted space, by Diakonoff,[9] by Bessel-Hagen,[10] and by Karavodine.[11] The latter interposes between the top of the pump-head and the exit-tube, F, a small chamber closed at the bottom by a valve consisting only of mercury standing over a capillary orifice, exactly resembling that previously described by Schuller, figure 20. This has the result of causing the last portions of residual air to be expelled into a space containing a moderately perfect vacuum. This is a decided improvement. For, as was pointed out with respect to the Sprengel pump, the air carried down the narrow fall-tube is necessarily compressed in order to drive it down against atmospheric pressure, and bubbles or films remain adherent to the glass.

In some modern modifications this is to a very large extent obviated, by the device of so bending the eject-tube or fall-tube, that the air expelled from the pump-head need only descend a very few centimeters down the tube before it enters a chamber that is partially exhausted. In short, if by any device—whether by placing it at the top of a fall-tube or by applying a good mechanical pump—a moderately good exhaustion can be maintained with a chamber such as that marked M, and this chamber is joined to the pump-head by a descending fall-tube; the length of this fall-tube need not exceed the height of a column of mercury representing the difference of pressures between the two chambers. In the diagrams that follow, such a shortened fall-tube is marked Q; it may be regarded as a sort of siphon air-trap. Such an arrangement has been independently devised by several persons. It was patented by Siemens and Halske[12] in Germany, in 1884. Figure 29 shows the device as originally designed. The pump-head terminates in a capillary tube, which turns over into a pool of mercury in the base of the upper chamber, M, into which the residual air is driven with a very slight compression. When a certain amount has thus been collected, it is expelled by further raising the mercury and opening the top tap, T, which is otherwise kept closed. A wider tube, Z, which should be usually closed by a tap, serves to return to the pump shaft the mercury which may have been driven over into M. A later form of this pump, depicted in figure 30, is used in Siemens and Halske's lamp factory in Berlin.

A similar device was suggested by Sundell,[13] who has further improved the arrangements at the bottom of fall-tube, so as to allow of other gases being admitted to the pump. Some of Neesen's pumps, and that used in the Weston lamp factory in Newark, also have this device; but these belong to the sub-class of shortened pumps, and are described below.

Mr. Swinburne,[14] who has had extensive experience with pumps of several kinds, has described a form in which this principle is applied. Swinburne's first form, though provided like Toepler's, with a fall-tube, had also an automatic valve above the pump-head. Figure 31, taken from Swinburne's paper in the *Electrician*, shows this valve situated above a small cavity, C, separated from the pump-head by a constriction, the object of which is to prevent the glass bottom of the valve being broken by the sudden rise of the mercury. The eject chamber, E, is connected through a tap, L, to a horizontal pipe, marked F in this cut. This pipe which runs along a whole range of pumps in the pump-room of the lamp factory is mechanically exhausted, and the use of the tap, L, is to start the action of the pumps. After this the action is kept going by a three-way tap (here marked K) which connects the cavity above the mercury in the supply vessel alternately with

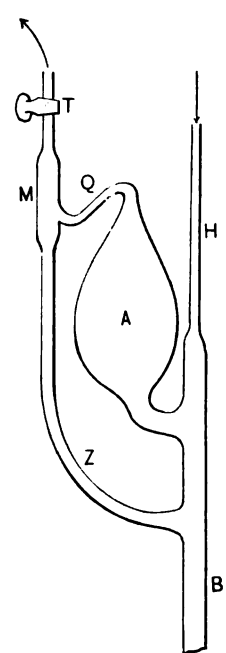

Fig. 30.

Siemens's Pump. (Factory Form.)

the atmosphere and a supply of compressed air. In a later form, Swinburne's pump has a siphon mercury-trap between the pump-head and the automatic valve above it. When the exhaustion

has been carried far enough, the mercury is lowered and raised some 10 or 20 times, just so far as to drive the residual air through the mercurial syphon, which will then show a small back pressure —perhaps of only one or two centimeters. If the volume of the pump-head is many times as great as that of the cavity beyond the mercury-trap, and if there be a fairly good vacuum beyond the trap, it is obvious that a back pressure of one or two centimeters as the result of 20 strokes may mean a very high degree of exhaustion. Swinburne remarks that the bore of the siphon tube used as a trap must be not larger in the descending part than in the part that ascends to the supplementary chamber.

CLASS III*a*.—SHORTENED UPWARD AND DOWNWARD-DRIVING PUMPS.

Swinburne's pump just described might, if worked intermittently with an exhausting instead of a compressing pump, be transferred to the category of shortened pumps.

Probably the more perfect of pumps in this class is that of Professor F. Neesen,[1] of Berlin. This indefatigable worker has introduced, from time to time, several improvements. As mentioned above, he introduced the side-tube, N, in 1878, and designed a double-acting Toepler pump in 1880. Independently of Mitscherlich, he introduced the automatic valve above the pump-head. In 1882 he was already employing the recurved siphon trap, Q, between the pump-head and the second chamber, M. His complete pump, as constructed in 1887, is shown in figure 33. The lower portion is constructed on Robinson's plan, airtight connections being formed at the three necks of the bottle, L, by the use of coned steel collars, that are cemented to the three tubes, and fit to coned adapters, cemented to the three necks. Steel screw caps clamp down the conical collars into their respective seats. The tube, Y, is put into alternate communication with the atmosphere, and with a good mechanical air-pump, so as to raise and lower the mercury alternately, in the pump-head, A. There is an automatic valve, U, in the exhaust-tube, which leads up to the drying flask and to the lamp or other vessel that is to be exhausted. This valve, which is shown enlarged in figure 34, is made somewhat on the plan of Schuller, described above, with a small glass disc about two centimeters in diameter, cut from thin plate-glass, which, as the mercury rises under it, is pressed up against a flat flange, fashioned on the lower end of the upper tube. It works in a manner that leaves nothing to be desired. This pump is further provided with a chamber, M, and a siphon-trap, Q, down which the residual air from the pump-head is expelled into a moderately perfect vacuum.

[2] Swinburne's Pump.

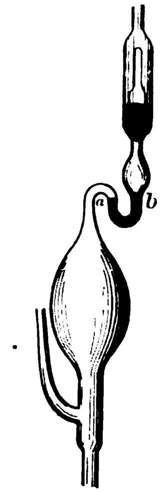

Fig. 32.

Swinburne's Pump. (Later form.)

Another very interesting and extraordinary pump belonging to this class is that of P. Clerc,[3] depicted in figure 35. The apparatus shown is connected by a flexible rubber tube to a mechanical pump capable of giving a moderately perfect vacuum. The apparatus consists of a disc of wood, round the periphery of which is fixed a glass tube, closed in itself, but provided with a

U-shaped bend to serve as an air-trap. At one side of this trap rises a short branch tube to which the lamp that is to be exhausted is sealed; at the other a similar branch tube leads to a bulb connected through a tap to the auxiliary pump. Enough mercury is placed in the tube to occupy about a quarter of the circumference and fill the trap. The whole apparatus is mounted obliquely upon another disc of wood, in such a way that it can be rolled round on its periphery by means of a projecting central handle. A preliminary exhaustion having been attained, the tap is closed and the apparatus is rolled around. The mercury in the tube sweeps the air before it into the bulb, and, passing into the trap again, emerges to push a fresh quantity from the lamp in front of it, leaving behind every time in the trap a sufficient quantity of mercury to balance the difference of pressure between the bulb and the lamp. The quantity of mercury required for this apparatus cannot exceed a few cubic centimeters at the most.

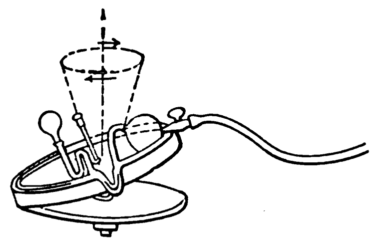

Fig. 35.

Clerc's Pump.

Figure 36[1] represents the pump used in the lamp factory of Mr. Weston, at Newark, New Jersey. The second chamber, M, connected with the pump-head by the siphon-tube, Q, will at once be recognized, as also the automatic valve, U, in the exhaust tube. The mercury in the supply-vessel, S, is raised and lowered by alternately connecting the upper part of the vessel through the three-way tap, Y, with a mechanical exhaust pump, and with the atmosphere. The top tap is only used when the chamber, M, has to be put into communication with the mechanical pump; the other taps are safety taps, not used during the working of the pump. The tap between the lamps and the valve, U, is worse than useless.

CLASS IV.—COMBINATION PUMPS.

It has been suggested by Edison[2] and by Böhm[3] to combine a Geissler pump with a Sprengel pump in the endeavor to obtain a more perfect result. This method of combination which consists merely in sealing the exhaust tubes of each pump together and to the lamp cannot be commended. If the Geissler exhausts more perfectly than the Sprengel, or *vice versa*, then the other pump is useless. A much more hopeful combination has been suggested by Mr. J. T. Bottomley,[4] who proposes to utilize a Geissler arrangement to exhaust the chamber into which the foot of the fall-tube of the Sprengel is led, thus putting the two pumps into series.

CLASS V.—INJECTOR PUMPS.

There are a few pumps depending for their action upon the principle of the injector, the degree to which they exhaust depending upon the velocity of efflux of mercury from an orifice, as in the original injector of Hauksbee. The earliest of these were designed by Cavarra[5] and Plateau.[6] Another form, exhibited in 1876 at South Kensington, was invented by Professor von Feilitzsch,[7] in which two cylinders fitted with pistons, worked by cranks, drove a mercury blast through suitable jets and drew in air, so creating a vacuum. It exhausted down to a pressure of one millimeter, or about 1,300 millionths of an atmosphere.

Several other injection pumps of the centrifugal species were described by de Romilly[8] in 1881, one of them being designated as a *pnéole*. Nothing is known to the writer as to its performance.

CLASS VI.—MECHANICAL MERCURIAL PUMPS.

Only one pump is known to the writer as coming definitely within this category; and this is a pump designed and constructed by Mr. J. Wimshurst, and of which no account has hitherto been published. It consists of an endless chain of little steel buckets, which pass up one barometric column and down another, within steel tubes containing mercury. Below, they enter a mercury bath, where they pass under two square pulleys, rising over a higher driving pulley between the two. The buckets as they descend, mouth downwards, carry down air from above the top of the barometric column, and discharge themselves as they come up in the mercury bath. Owing to the fact that it has hitherto been found necessary to employ oil as a lubricant, the power of this highly ingenious apparatus to produce a vacuum is limited.

There are a few pumps concerning which the writer has not been able to obtain information, including those of Diakonoff, Neveux, Pfluger, and Southby, which are known to him by name only.

RESULTS.

The results that have so far been obtained by various pumps may be briefly tabulated as follows: the vacua produced being specified both in millimeters and in millionths of one atmosphere.

If Rood's method of measurement be correct, the results attained by him are very remarkable.

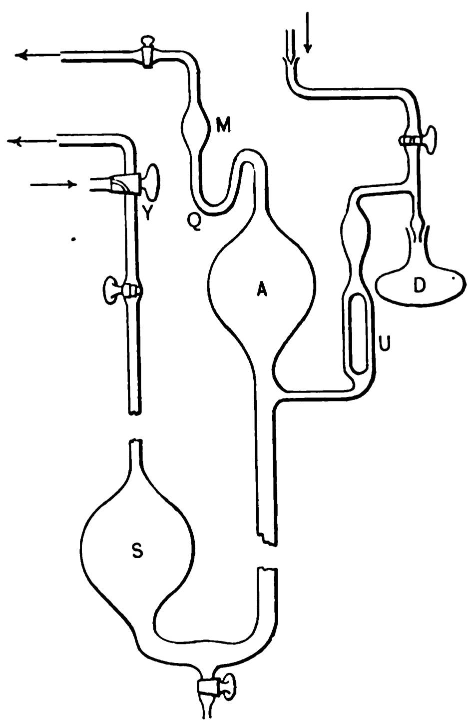

Fig. 36.

Weston's Pump.

Authority.	Nature of pump.	Pressure in millimeters of mercury.	Pressure in millionths of one atmosphere.
Crookes.....	Improved Sprengel (maximum result)............	0.000 046	$\frac{1}{17}$
Gimingham.	Single-fall Sprengel, 1.1 millim. diam...........	0.000 51	$\frac{2}{3}$

"	" after 5 more..	0.006 4	8
"	Modified Toepler (average)	0.000 012	$\frac{1}{63}$
"	" " (maximum result)	0.000 008	$\frac{1}{95}$

CONCLUSION.

On comparing the experience of various workers, it seems as if the best class of pump for the production of such vacua as are required for lamps is the third class, as modified so as to drive the air up the pump head and down a simple short barometric trap into an already partially exhausted chamber. No one appears to have yet tried a shortened Sprengel with a crook in the fall-tube. The writer offers it as a suggestion. Further, if the experiments of Rood are worth anything, they indicate that an immense advantage is gained by working with pumps heated up above the boiling point of water. The "adsorption" of gases and vapors against the surfaces of glass and mercury in the working parts of the pump is certainly much less hot than cold. Why should not all pumps be so constructed as to enable this method to be adopted? Since much seems to depend on the purity of the mercury, why should not the mercury be distilled direct into the pump? Whenever cements are used, why should not some plastic inorganic substance, such as chloride of lead or tungstate of lead be employed, instead of resin, pitch, or other organic body, which will give off vapors. Lastly, if the device of exhausting into an already fairly well exhausted chamber so greatly improves the degree of rarefaction attainable, why should we not carry this process one or two stages further, and relay a series of pumps one working into the other? Such a process would resemble those processes of successive operations which have been called "Pattinsonization;" and it is possible that it might yield results surpassing anything yet attained.

In surveying the literature of the mercurial air-pump one cannot but be struck with the immense number of workers who have contributed to the invention and the number of details that have been independently reinvented by different individuals. The literature of the mercurial pump affords, indeed, a striking proof of the fact that inventions grow rather than are made. The invention is essentially the product of the age in which it appears, a necessary consequence of the inventions and discoveries that have preceded it. The scientific method of investigating historical events has shown us how false, how childish, is the "great man" theory of history, which was taught—and alas! is taught still—to us at school. But if the great man theory of history is fallacious, so is also the great man theory of inventions. There were steam engines before Watt, locomotives before Stephenson, telegraphs before Wheatstone, telephones before Bell, gas engines before Otto. It may be that occasionally an inventor strikes upon a valuable or useful improvement; it is exceedingly rare for an absolutely original invention to be sufficiently perfect to be of immediate use. Of the essential insufficiency of the great man theory of inventions, the literature of the mercurial air-pump affords a most striking proof.

The investigation of this literature, which has long occupied the writer, has been a fascinating pursuit, partly because of its unexpected richness, partly on account of the fascination of the subject. Everyone who has worked with mercurial air pumps must acknowledge to a kind of fascination in watching the ebb and flow of the liquid metal, and in speculating on the nature of the actions that go on in the vacuous spaces. It was, perhaps, with some such sense that Hauksbee, after describing one of his physico-mechanical experiments, wrote these words :—"Such a dense and polite Body is Mercury; such a subtle Mover is Air; and such an apt Repository is an Exhausted Receiver."

SIR WILLIAM THOMSON'S NEW STANDARD ELECTRICAL MEASURING INSTRUMENTS.[1]

BY J. A. FLEMING.

FOR the last six years, Sir William Thomson has been engaged in developing and perfecting a complete series of instruments for the measurement of electric currents. Beginning with the now well-known graded galvanometers, he has finally accomplished the task of providing a connected group of instruments, which may be broadly classified into three divisions: (1) Standard direct reading electric current balances; (2) magnetostatic galvanometers or lamp counters; (3) marine and engine room voltmeters. The standard direct reading electric current balances are standard instruments, in which every source of possible error arising from the use of permanent magnets or soft iron is eliminated, and the operation of these instruments consists entirely in weighing, by means of standard weights, the attraction or repulsion between movable and fixed coils of wire conveying electric currents. These standard current balances may be said to be modifications of the electro-dynamometer, which was first described by Weber in his "Electro-dynamische Maasbestimmungen" (Leipsic, 1846). The foundation of the electro-dynamometer was, however, laid long previously. On 25th September, 1820, André Marie Ampère announced to the Royal Academy of Sciences, in France, that he had discovered the existence of forces of attraction and repulsion between conductors of non-magnetic material traversed by electric currents. The experiments of Ampère and the elaborate researches of Weber (W. Weber, "Electro-dynamische Maasbestimmungen, Thl. I., s. 10, 1846, Auszug in Pogg Annal, Bd. lxxiii., s. 193), established the fact that if there be a fixed and a movable conductor in the neighborhood of each other, traversed by the same electric current, there will in general be a mechanical stress brought into existence, which will tend to displace the movable conductor, and bring it into a position relatively to the fixed conductor in which the mechanical stress between them is zero. The mutual force or stress between these mutually influencing portions of the same circuit is, in any given position, proportional to the square of the strength of the current traversing the two portions of the circuit. In Sir William Thomson's standard instrument this stress is measured by comparing it with or balancing it against the weight of certain standard masses; in other words, the electro-dynamic stress is compared with the gravitation stress on a given mass.

The great difficulty which has hitherto presented itself to all who have attempted to design instruments on the electro-dynamometer principle for any but very small currents has been that of getting the current into and out of the movable conductor. The device on which most experimentalists have fallen back is that adopted by Ampère himself, viz., to use mercury cups as a means of constructing a flexible and conducting joint. The use of mercury is open to many objections. The surface gradually becomes oxidized, the cups must be filled and emptied each time, the instrument has to be transported, and the joint with impure mercury is by no means exceedingly flexible. The great achievement in these instruments has been, first, the invention of a joint or electric coupling which is excessively flexible, and at the same time capable of being constructed so as to carry with safety any current desired. This has been accomplished by the introduction of a device which may be called a metallic ligament. The general principle of its construction, and the mode of rendering a circuit freely movable, yet accessible to a large current, may be described as follows: Let A A (figure 2) be a pair of semi-cylindrical fixed trunnions, which are carried on some form of supporting frame, and held with the flat sides downwards. Let B B, be two similar trunnions, which project out from the sides of two strips, connecting together a pair of rings, C C. The pair of rings and the connecting strips constitute the circuit which is to be rendered movable. A current entering by the trunnion + B flows round the two halves of the circuit, as shown by the arrows, and emerges at the trunnion — B. In figures 2 and 3, the current is shown dividing round the two rings; but we should explain here that this has been done by an oversight. The circuit should be shown so that the current goes round both rings in series, in figure of 8 fashion. This is the case in all but the kilo- and hekto-ampere balances, in which the current divides round the ring. To the upper surface of the upper trunnion are soldered a very large number of exceedingly fine copper wires (No. 60 B. W. G.), which are laid close together. These wires are also soldered to the under surface of the lower trunnion. The movable circuit C C, thus hangs from the upper trunnion by two ligaments, which appear like thin strips, but which are really composed of an immense number of very fine wires. In figure 2, these ligaments are intentionally drawn much longer in proportion to the rest of the figure than they really are in the instrument, the object being to render the mode of suspension clear. This method of suspension enables the conductor C C, to vibrate freely like a balance by a motion which is partly a bending of the flexible ligaments, and partly a sort of rolling and unrolling of the lower trunnion on the ligament attached to it. By this ingenious method not only can a heavy

1. Reprinted from *Industries.*

copper conducting circuit of the shape shown be suspended as freely as the beam of a good balance, but at the same time a very large current density can be permitted in the flexible ligament, since its great radiating surface, and the freedom with which heat is taken out of it by conduction into the mass of the trunnions, allows a proportionately very large current to be transmitted. If, then, the trunnions A and B are the electrodes, the method above described affords the means of passing a very large current into the circuit C C, which yet at the same time retains within certain narrow limits great freedom of movement. Let such a suspended conductor be arranged so as to have a circular conducting circuit of annular form, briefly called an ampere ring, placed above and below each of the movable rings of the balanced arm. Let the connections be made as shown diagrammatically in figure 3, in which it will be seen that the current entering by the + electrode flows in series through all four fixed ampere rings F, and in parallel through the two movable ampere rings M. An examination of the direction of current flow in each ring will then show that, in consequence of Ampère's law (parallel currents in same direction attract, in opposite direction repel), forces of attraction and repulsion will be brought into play between each fixed ring and the movable rings, which tend to lift one ring, M, and depress the other, and tilt over the balance arm to which they are attached. The amperian forces thus exert a couple on the movable part. To bring back the movable part to its initial position, which we may suppose to be half way between each fixed ring, an equal and opposite mechanical couple must be applied. We shall in what follows call the movable part of the conducting circuit the balance coils, and the other portion of the circuit the fixed coils. The operation of weighing an electric current consists, therefore, in (figure 4). On the base board of the instrument, and just underneath the shelf on which the weight slides, is placed a little metal block, which carries a stout vertical wire extending a little above the shelf carried on the balanced beam. From the top of this wire is carried a pendant wire, which hangs down through a notch in the weight which slides on the shelf. This block, carrying the pendant, is pulled along the railway by a silk cord. When pulled it drags with it the weight on the shelf; but when the string is released the pendant returns to its vertical position and disengages itself automatically from the weight, leaving the balance free to tilt according to the direction of the forces acting upon it. By this means the weight can be shifted along until a balance is obtained, whilst at the same time the whole balance is covered with a glass case to protect it from currents of air. With each current balance three sliding weights and three corresponding counterpoises are provided, the weights being in the ratio of 1, 4, 16. Thus if with the ampere balance the lightest weight on the sliding tray in a certain position corresponds to a current of half an ampere through the instrument, the next weight at the same place corresponds to one ampere, and with the heaviest weight on it the current is two amperes. The upper edge of the shelf on which the weights slide is graduated into equal divisions, and the weight is provided with a sharp tongue of metal, in order that its position on the shelf may be readily and accurately determined. For the purpose of avoiding continual reference to square root tables, another fixed scale is placed behind the shelf, called the inspectional scale. On the upper edge of the shelf, along which the graduations are made, a small notch is cut at those divisions whose numerical denominations are exact squares; thus corresponding to divisions 1, 4, 9, 16, 25, 36, &c., on the scale en-

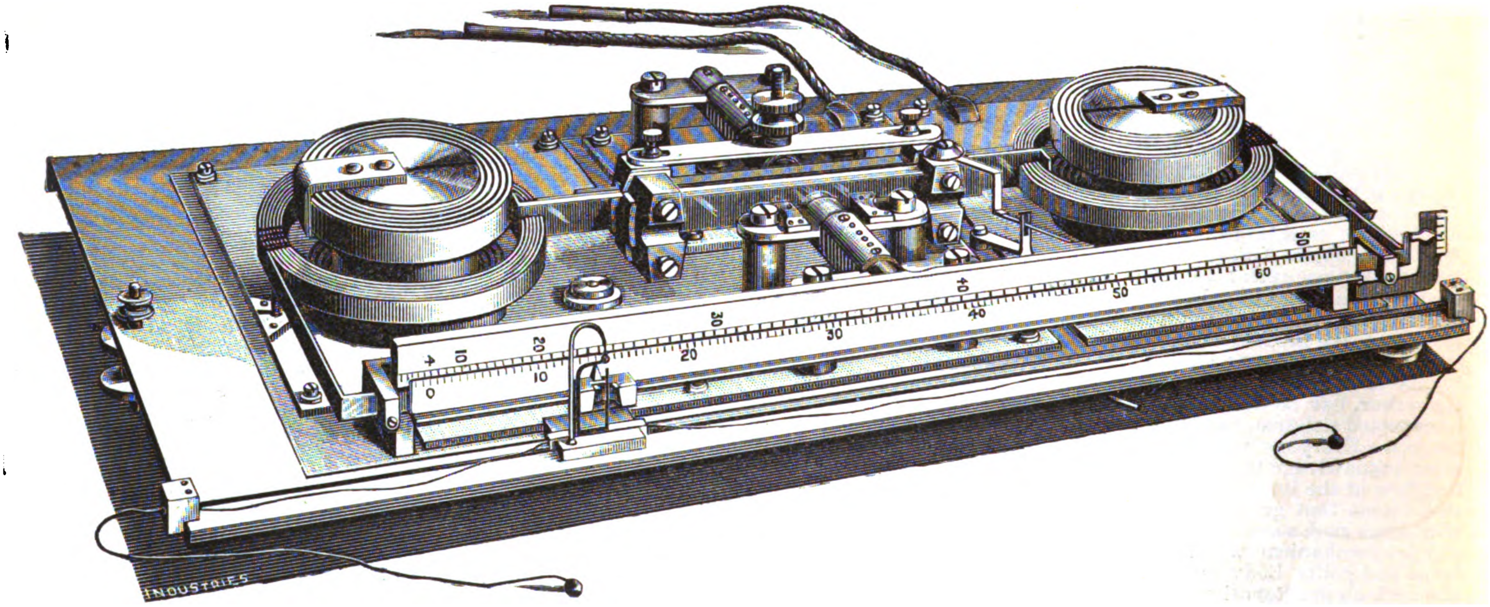

Fig. 1.

bringing first of all the balance coils into a definite sighted position between the fixed coils, then passing the current and bringing back the balance coils into the sighted position against the displacing electro-dynamic forces by applying to the balanced part a couple produced by a standard weight. The restoring couple is applied as follows: Attached to the balanced part or movable portion is a stiff metal bar, turned up at the bottom edge so as to form a sort of long shelf. This shelf or tray extends the whole length of the movable beam, and moves or tilts with it when the balanced part is displaced (see figure 1). At one end of the balanced part, at the extreme right of our illustration, is a small V shaped tray, in which a weight is placed. A standard weight is then placed at the opposite end of the shelf. This weight is of such form as to slide along the shelf easily (see figure 4). When placed at the zero position on the shelf it exactly balances the counterpoise in the V trough, and the balanced part should be in equilibrium when no current is passing. If it is not so, then a small adjustment can be made by means of a metal flange on the beam (figure 1), similar to that on a gravimetric balance. If the sliding weight on the shelf is moved along towards the middle the equilibrium is disturbed and a couple brought to bear upon the balanced part, which is proportional to the displacement of the sliding weight from its zero position. If a current is passed through the circuit, and the sliding weight displaced so as to restore the balance to its sighted position, the current strength is proportional to the square root of the distance by which the sliding weight has to be shifted in order to restore equilibrium. The shifting of this weight is performed by a very ingenious piece of mechanism, which will be understood from the enlarged view graved on the shelf are cut little notches in its upper edge. The inspectional scale is fixed close behind this, and yet not touching, and at those points on it exactly behind the notches are engraved numbers which are twice the square roots of the corresponding numbers on the shelf; thus corresponding to 1, 4, 9, 16, 25, &c., on the shelf the numbers 2, 4, 6, 8, &c., are engraved on the inspectional scale. Since the current passing through the balance when equilibrium is obtained with a given weight is proportional to the square root of the couple due to this weight upon the balance, it follows that the current strength when equilibrium is obtained is proportional to the product of the square roots of the weight used and of the distance of this weight from its zero position; but the inspectional scale is so graduated as to show at a glance the square root of the distance of the weight from its zero position, and hence the numbers on the inspectional scale indicate half amperes, amperes, or double amperes, according to the weight used.

The fixed inspectional scale shows approximately enough for many purposes the strength of the current; the notches in the top of the aluminum sliding scale or shelf show the precise position of the weight corresponding to each of the numbered divisions on the inspectional scale, and practically annuls error of parallax due to position of the eye. When the pointer on the weight is not exactly below one of the notches corresponding to integral divisions of the inspectional scale, the proportion of the space on each side to the space between two divisions may be estimated inspectionally with accuracy enough for all practical purposes. Thus, we may readily read off 34.2 or 34.7 by estimation, with little chance of being wrong by .1 in the decimal place. But when the utmost

accuracy is required, the reading on the fine scale of equal divisions must be taken, and the strength of the current estimated by aid of a table of square roots supplied with each instrument.

These general principles being understood, we proceed to describe the details of the several types of instruments adapted for

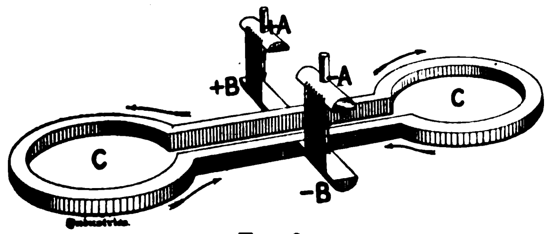

FIG. 2.

various ranges of useful measurement. The range of each instrument is from 1 to 50 times the smallest current for which its sensibility suffices. The ranges of the different types of instrument regularly made are:—

The Centi-ampere	balance	from	1 to	50 centi-amperes
" Deci-ampere	"	"	1 to	50 deci-amperes
" Ampere	"	"	½ to	25 amperes
" Deka-ampere	"	"	2 to	100 "
" Hekto-ampere	"	"	10 to	500 "
" Kilo-ampere	"	"	50 to 2,500	"

Figure 5, shows the general appearance of the centi-ampere, deci-ampere, ampere, and deka-ampere balances. In these instruments the outer diameter of the fixed coils is slightly greater, and the inner diameter less than those of the movable rings attached to the balance arms. The position of the movable rings when in equilibrium and equi-distant from the fixed ones above and below it, is a position of minimum force, and the sighted position for the sake of stability is above it at one end of the beam and below it at the other, in each case being nearer to the repelling than to the

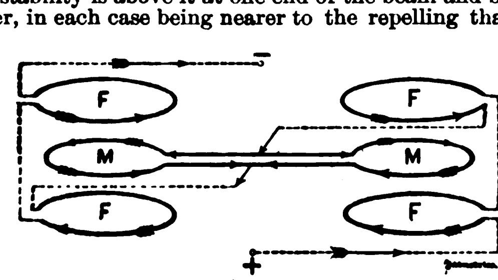

FIG. 3.

attracting ring by such an amount as to give about $\frac{2}{10}$ per cent. more than the minimum force. In order to adapt these balances for alternating currents, a special mode of arranging the conducting circuit has to be adopted. In the balances intended for alternate currents (which may be used also for direct currents) of from 5 amperes to 250 amperes, the main current through each circle, whether consisting of one turn or of more than one turn, is carried by a wire rope, of which each component strand is insulated by silk covering or otherwise from its neighbor, in order to prevent the inductive action from altering the distribution of the currents across the transverse section of the conductor; whilst to avoid induced currents in these parts the coil frames and base board are

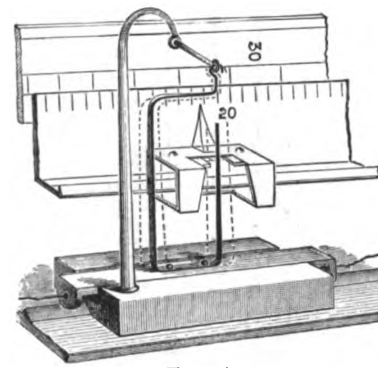

FIG. 4.

constructed of slate. The hekto-ampere and kilo-ampere balances are slightly different in arrangement from the foregoing. In these the whole current to be measured is passed through a single fixed ring and then divides through the two halves of a movable ring, which are urged, one up and the other down, by the resulting amperian force. The largest balance yet made is one for measuring currents up to 2,500 amperes, constructed for Messrs. Paterson and Cooper. The centi-ampere balance (figure 5) is provided with a thermometer to test the temperature of its coils, and it may be used as a voltmeter when provided with platinoid resistance coils, which make it available for the measurement of potential difference from 10 up to 200 volts or more.

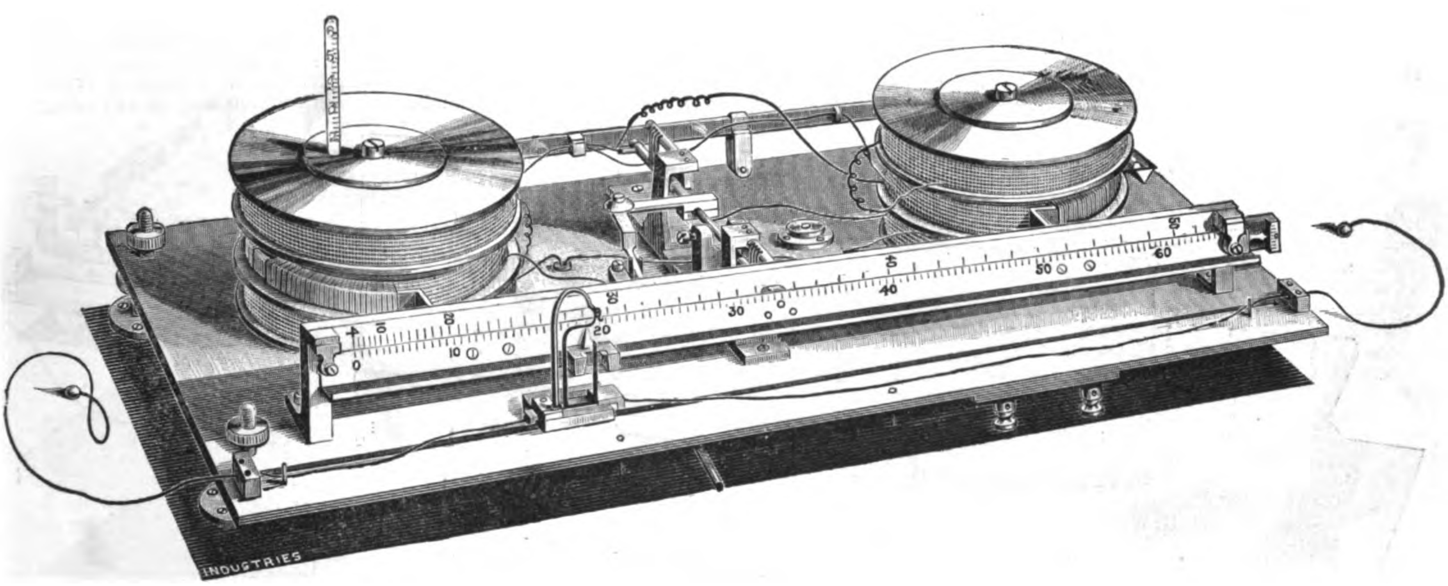

FIG. 5.

The direct reading engine room voltmeter is an instrument based upon the same principle, but which indicates potential difference between certain limits without the performance of any operation of weighing. This inspectional voltmeter (figure 7) consists of a fixed platinoid resistance, which is in series, with a fixed and movable ampere ring. On the base board of the instrument is fixed horizontally, a single coil of highly insulated copper wire. Over this, and suspended parallel to it, is a movable coil, carried at the end of an aluminum rectangular frame, which is suspended by ligaments near the opposite extremity. The weight of the coil is counterbalanced by adjustable weights, so that its normal position is parallel to and a little removed from the fixed coil. When these three coils (viz., the platinoid resistance coil below the base board, the fixed coil, and the movable coil) are traversed by one and the same current, the electro-dynamic repulsion lifts the movable coil, and raises it slightly from the surface of the fixed coil, on which it rests when no current is passing. If the current through the coils is slightly increased, the movable coil is repelled a little more; and if it is diminished, it is repelled a little less. These small movements of the coil are multiplied by a lever, the long arm of which moves over a scale, and the short arm of which is connected by a stiff wire with the balance bar carrying the coil. The fixed and movable ampere rings are each composed of many

turns of fine insulated copper wire, having a total resistance of 100 ohms. The amount of added platinoid resistance depends on

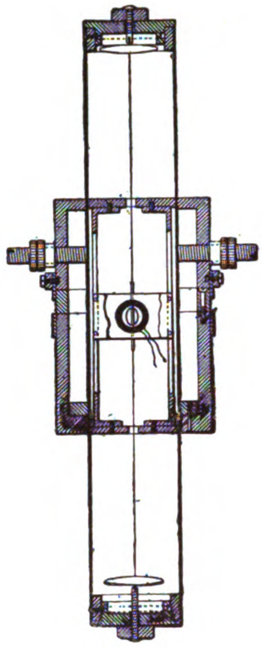

FIG. 6.

the potential to be measured in the ordinary use of the instrument. Thus for potentials of from 10 per cent. below, to 10 per cent.

marine voltmeter consists of a small oblate spheroid of iron, resembling a small round bean or flattened pea. It is attached to the middle of a platinoid wire, which passes through its equator, so that it is suspended with its equatorial plane vertical. If such an oblate is placed in a magnetic field, it will endeavor to place the plane of its equator in the direction of the lines of force of the field; and the couple required to hold it in any given position will depend upon the mass of the iron, and the form and strength of the field. In the marine voltmeter the magnetic field is created by a current circulating in a coil of copper wire in series with a set of platinoid resistance, variable according to the potential to be measured. The platinoid wire carrying the oblate is stretched by attaching it to the ends of a tubular support, whilst the oblate carries a pointer which moves over a dial. The magnetic field due to a current in the coil is a uniform field, and the zero portion of the oblate is, with its equatorial plane, inclined at an angle of about 45° to the lines of force. The platinoid wire bearing it is arranged so that its torsion tends to turn it into a position at right angles to the lines of force. This tendency is resisted by a stop against the needle, so placed that when no current, or any current less than 90 milliamperes is passing through the instrument, the needle remains at the end of the scale. When a current exceeding 90 milliamperes is passing through the instrument, the E. M. F. operates against the torsion, and turns the oblate into a definite position in the field. The position of the oblate is thus a measure of the current passing through the instrument, and hence of the potential difference at the terminals of the coils. When the mean potential difference to be measured is 100 volts, the platinoid resistance is adjusted to make up with the fine copper wire solenoid, the resistance of which is about 60 ohms, a total resistance of 1,000 ohms. Thus the direct reading of potential on the scale is in volts.

Another instrument for use in electric light installations is the adjustable magneto-static current meter and lamp counter. This instrument is a convenient modification of the well-known graded galvanometers. It is a direct reading galvanometer, and has certain advantages over the electric balances in portability, and in being direct reading through a continuous range of from 1 to 90 or 100 times its smallest current, which may be anything

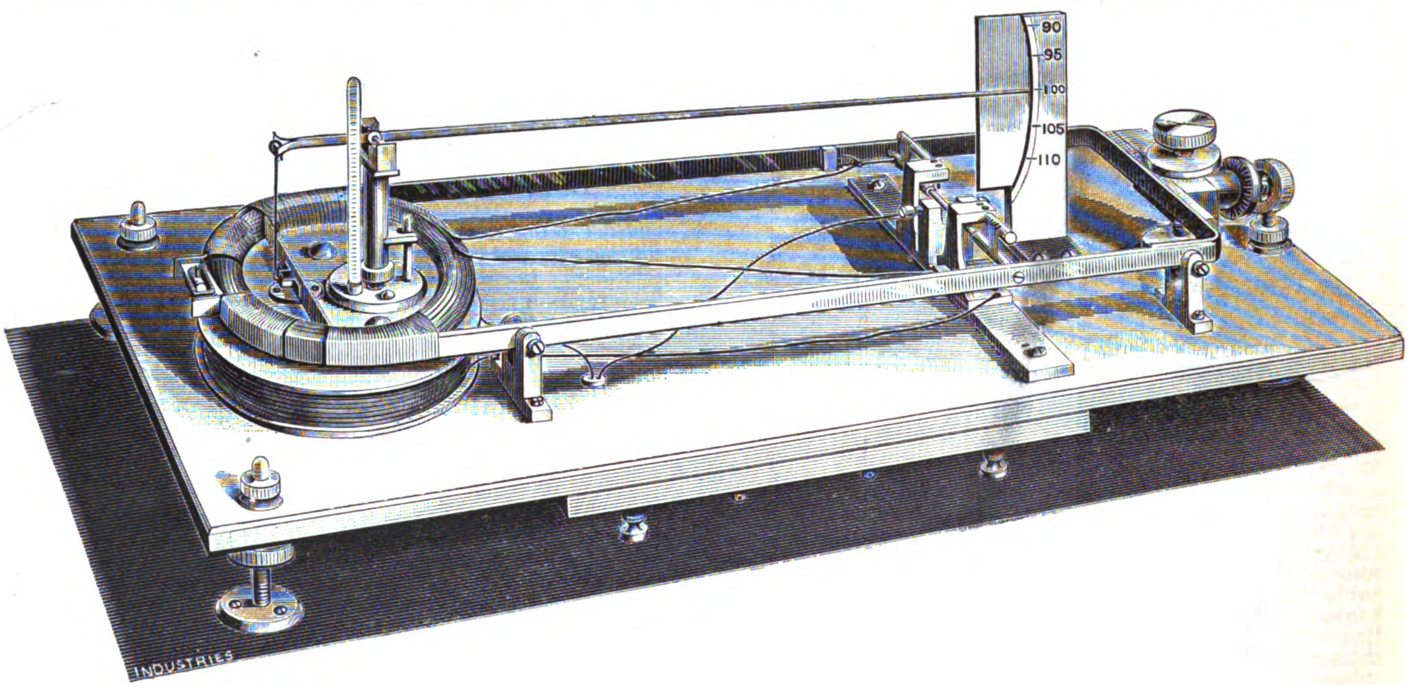

FIG. 7.

above 100 volts the platinoid resistance is 700 ohms. The scale is divided so as to indicate directly in volts. The instrument is specially designed for use as an engine room voltmeter, and indicates directly, within allowable limits, the excess or deficit of E. M. F. from the normal. Temperature error is annulled by providing a thermometer, placed in the coils, and a set of compensation weights. Four weights, corresponding to centigrade temperatures 15°, 20°, 25°, 30°, are supplied, and when the thermometer indicates any atmospheric temperature between these limits, the weight most nearly corresponding to that temperature is placed in the V trough attached to the end of the balance bar on the left. When not in use, the weights are kept in little receptacles marked with the temperature, so that no mistake can be made in seeing which is in use.

The marine voltmeter (see figure 6), is an instrument designed for use at sea. The foregoing engine room voltmeter, and the deci- and centi-ampere balances, are not suitable for this purpose, as the mass of the moving part of the balance is too great. The

from half a milliampere to one ampere, according to the number of turns in the coil supplied with the instruments. The general design of the instrument may be described as follows: Underneath a circular dial plate are fixed a pair of semi-circular coils, which may consist of many turns of wire or of a massive copper bar, according to the strength of the current to be measured. Centrally beneath the dial plate is a short glass tube, in which is suspended a circular disc of magnetized steel. The suspension of this disc is very ingenious. On the surface of the dial plate is fixed a piece of platinoid spring, and from this depends, by a short cocoon fibre, an aluminum needle, which is carried on the same vertical axis as the magnetized disc. If the cocoon fibre were attached to some rigid support any shaking of the instrument would be certain to break it; but suspended as it is from a yielding and flexible support, any jolt or shake causes the spring to yield sufficiently to let down the needle on to the dial plate, and so saves the cocoon fibre from fracture. Underneath the coils is attached a permanent magnet which creates the controll-

ing field. The instrument thus virtually consists of a galvanometer with a powerful controlling field, and in this respect it has all the disadvantages of this class of apparatus: in not being available for alternate currents, and in that the value of the deflections is dependent upon the permanence of a steel magnet. With a good quality of steel and a proper ageing of the magnet (by heating it several times in boiling water and cooling it again, and subjecting it to somewhat varied rough usage), a very nearly permanent condition is reached, and its magnetism will probably remain constant from year to year. Still it can never be relied upon as absolutely constant, and hence the magneto static instruments require from time to time to be re-adjusted by the aid of a balance instrument, the adjustment consisting in shifting the controlling magnet. The scale has 100 divisions, corresponding to equal differences of tangents of the angle between the magnetic axis of the needle and the electro-magnetic axis of the rings. The divisions may be numbered from 0 to 100, but for many purposes it is convenient to number them from 30, 20, or 10 on the left of zero, and from zero to 70, 80, or 90 on the right; because we have thus larger divisions in the neighborhood of the zero than when it is taken at the extreme left of the scale, and because it is sometimes convenient to measure small currents in the direction opposite to that of currents ordinarily measured. The scale being so divided that its divisions indicate equal increments of current through the coils, it is possible to set the magnet beneath the coils, so that the unit of current shall be within certain limits of what is desired. It may, for example, be one milliampere, one ampere, or a tenth of an ampere; or, more convenient still, it may be made equal to the average current through a lamp on the installation in connection with which the instrument is used. It becomes thus a lamp counter, and when put on the circuit shows at once the number of lamps in actual use at that instant. The

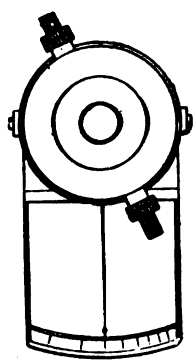

FIG. 8.

instrument may be made with such massive coils as to count lamps up to a thousand or more. When the instrument is used as a lamp counter, primary adjustment or re-adjustment can be performed at any time with great ease by turning the screw platform which bears the adjusting magnet, so as to raise it or lower it until it is found that the deviation from zero produced by the current of any number of lights shows a corresponding number on the scale of the instrument. With scales numbered from 1 to 90, any number of lamps within these limits can be directly counted by inspection; and for greater numbers of lights the instrument can be set to count by 5 or by 10, so that the attendant knows at any instant the load on his dynamo by simple inspection. The instrument must be, however, removed as far as convenient from the neighborhood of the dynamo, or else calibrated in the position in which it is to be used. The most convenient instrument of the complete series for an ordinary installation or workshop would be the deci-ampere balance, which measures from about one-tenth to five amperes, and a magneto-static galvanometer reading from 1 to 100 amperes. The magneto-static instrument can then at any time be re-adjusted by the aid of the balance. This is simply performed by placing the instruments in series on a circuit and passing a current of five amperes through them. The current should be adjusted until the deci-ampere balance indicates exactly five amperes, and then the magneto-static instrument set by raising or lowering its controlling magnet until its needle points exactly to five on the scale when the current is on, and to the zero of the scale when the current is off. At the last meeting of the British Association Sir William Thomson stated that the balance instruments have a sensibility of one-tenth per cent. over a range of something like 1 to 25 times the smallest current they are designed to read; but it should be understood that the balances may be used for double these currents with a slight sacrifice of accuracy.

ABSTRACTS AND EXTRACTS.

THE FUTURE PROSPECTS OF THE GAS INTERESTS.[1]

BY THOMAS WOOD.

THOSE who were in attendance at our Dayton meeting will perhaps recall the fact that the writer at that time strongly advocated gas companies taking hold of the electric light and running same in conjunction with their gas business; you will also recall the fact that the writer suggested also gas companies taking up the incandescent electric light and fuel gas. Since that time it has been demonstrated by several gas companies in this and other states that the electric arc system can be added with success, financially, to gas companies and with satisfaction to their patrons, and the writer derives great pleasure in hearing of so many companies who have left the narrow and beaten track of prejudice and are now walking in the broad road of progression.

It is not my intention to dwell upon arc lighting only long enough to state that after two years practical experience with the combination our company consider they have taken a right step in adopting it and that it is satisfactory in every respect. Other gas companies who have adopted the arc system can undoubtedly corroborate this with their experience. I would make this paper a continuation of the last one by taking up the incandescent electric system and fuel gas question. That both will be introduced into every city in the United States before long by someone, I have not a shadow of a doubt, and why? Simply because they are both desirable commodities in domestic economy and hygiene.

Please lay aside all prejudice and I will show you an ideal domestic burner for illumination purposes. Now what comprises an ideal burner for domestic use? In the first place, such a burner must not blacken our walls and ceilings, neither must it give off deleterious products of combustion; it must be a steady light and not subject to draughts; it must not give out heat in summer; it must not be possible for inflammable goods to ignite by coming in contact with it; it must be a light that will have no ill effect if by accident the key is left open; it must be a light that our country cousins cannot blow out; neither must it be one that requires dangerous matches to ignite it; and lastly it must be a fairly cheap light. Now, gentlemen, if you have thrown prejudice to the winds, perhaps you can recognize in this ideal burner the incandescent electric light for domestic use. Now, if this light is an ideal burner, who is going to prevent its adoption by the public? Gas companies cannot, and if they cannot, no one can; so in my mind the wisest course to pursue is to admit what we know to be true, and proceed at once to supply the demand, increase our revenue, push out into the suburbs of our cities, sell it as cheaply as possible, and don't let others come in and take away what rightly belongs to you. If there is any money to be made in the business by others there is still more in it for us.

For store purposes, where the hours of burning are defined, I think it better to abandon the meter system and fix a price per annum or month for each lamp, taking into consideration the hours of use as a basis for charges. For private dwellings this would not be practicable, and we would have to resort to meters, or perhaps fix upon a price for furnishing the current and have the consumer purchase the lamps when renewals were needed; in this way economy would cheapen the light to the consumer. Any method that will dispense with the meter, and still be satisfactory, will be the one to adopt.

I cannot understand how some gas companies who have the incandescent electric system as a competitor can console themselves with the fact that it is not injurious to their gas business, even taking it for granted they are still selling as much gas as before its advent. Is this a reason why they should make no effort to secure their old patronage? I think not, for it is human nature to secure a whole loaf in place of the half when it is possible to get it.

A gas company's revenues would certainly be increased by the step, and a dangerous rival made profitable.

I think it is a mistake to think that by and by the people will get back to gas; of course, some will, just as gas consumers sometimes go back to coal; but because a few give it up, don't let us deceive ourselves by thinking all will do so eventually, for the incandescent electric burner is bound to remain wherever it is now in use, and will find its way to the other places where it is not now in use. That's all very well to talk about, I hear someone say, but what are they going to do with our prior investment? To such I would say: Push that, to cheapen it to its lowest point, and urge its use for power and cook stoves until such time that you find yourselves able to supply gas for heating purposes of all kinds.

1. Read at the Fourth Annual Meeting of the Ohio Gas Light Association, Sandusky, O., March 22, 1888.

What difference does it make to a company whether the money expended for improvement account be for coal benches, holders and mains, or dynamos, boilers and wire? I fail to see the difference, and if improvements have to be made in both, so much the better; it shows a healthy demand for both branches, and should be promptly provided for.

If arc lighting is to be the light on our streets and the incandescent electric lights for our stores and dwellings, shall we draw our fires and stop making gas? This, to the writer, would be an absurd deduction. It is for us to take things we find in nature's laboratory and select the fittest articles for each special use, and it is reasonable to suppose that it will be only the fittest that will finally be a success. The arc light, so far as the writer has ascertained, has asserted pretty generally throughout the country its supremacy on our streets, and this, in spite of all opposition from gas companies, showing conclusively that it has gained its position by the force of demand for the fittest. Incandescent electric light is just as surely finding its position and field of usefulness and in its turn will assert its supremacy; and why? Because it has the qualifications called for in the public specifications. Some will assert that it is too expensive to come into general use, and also that it is not as reliable as gas. The first is no argument against it, for was not coal gas sold at exorbitant prices in its early day? It certainly is capable of being cheapened in the future, as gas has been, and this is one reason why gas companies should enter the business, as it is in their power to cheapen it.

As far as reliability is concerned that certainly seems the most serious weakness, but don't be alarmed on that score, for, duplicate machinery or storage batteries will eventually overcome this bugbear; and while discussing this subject don't let us forget that the breaking of a main or filling up of a drip, a flood or explosion, or even Jack Frost has often caused our customers to think that even gas is not very reliable.

I cannot understand what gives gas companies as a rule their prejudice against electric lighting, unless it be that they imagine the outcome to be idle gas mains and cold benches. This I think is all wrong. The largest unoccupied field to day is the fuel gas field, and who should step in and supply this demand? Could anyone do it as well as the present gas companies? We have our mains and services already laid; we have our holders, meters, and trained labor; most of us have also the necessary land to spare on which to erect generators.

Next to the fuel gas field I think I can see another field nearly as extensive, and that is the coal-oil field.

Please imagine the following picture, which is representative of the writer's belief of what a gas company will be in the near future—in fact so near in the future that before our next convention rolls around it will be a reality.

One set of officers, whose principal qualification shall be progressiveness, their duties to be divided between electric lighting of all kinds, including electric power, fuel gas for all purposes, including gas engines; also incandescent lights off fuel gas mains.

Now let us see what the plant will consist of: One set of mains for fuel gas, from which our patrons will draw all their fuel, and also light if they wish. Gas engines will be run economically with this gas. One set of meters only will be required.

There will be no coal gas benches. The generators of the future will be on the cupola style, feeding by gravitation from the top. Native coals in all probability will be sufficiently good to make gas of. One portion of the plant will be devoted to the dynamos and engines for furnishing the electric light. Where the coal gas benches now are will be boilers, or perhaps even these will be unnecessary if gas engines be used. If steam boilers be used, they will be fired with producer and gas; the boilers will become simply pressure regulators. The revenues of gas companies will be increased five-fold if not more, the consumer will get cheaper fuel, cheaper power and cheaper light.

Native coal fields will become more valuable, and we will not pay tribute to other states as heretofore. The change from illuminating coal gas to fuel gas will perhaps be a slow one, owing to the conservatism of gas companies and imperfected details, but eventually it will be brought about in spite of all obstacles. If a company is operated as pictured it will furnish arc lighting, incandescent electric lighting and electric motors, fuel gas, incandescent gas lighting and gas engines.

Gas will be made on a larger scale, with less dirt and nuisance and without that laboriousness now necessary. Valves, levers and push buttons will displace scoop, drawing book and wheelbarrow, and the employés will no longer be known as "gas house terriers," but will become elevated to a higher plane. The officers of the company will also, of necessity, have to be more active and alert, and the rule of thumb will be at a discount. Now let us see where the gas man will be who fails to occupy these new fields of pasture green.

He will, of course, go on making coal gas in the old way; he will still wrestle with stopped stand-pipes, steam-jet exhausters, naphthaline, and worry over how much a bushel of coke weighs. He will try to convince his customers that he knows better than they do what they want and that anything but his gas is of no account; he will also keep on cutting out items from the newspapers whenever he finds it recorded that an electric light somewhere failed to flicker.

He will still maintain that there is not a company in the country making anything out of electric lighting; and it is only a matter of time when some fellow slips into his town and noting things, works up an arc light company, captures the street lighting and some of our friend's best consumers. The price of gas is lowered, all kinds of patent gas burners are invented to recapture those lost consumers, a fight ensues, factions are made in the town, and the arc light company adds an incandescent plant to that of arc light and captures more of our friend's consumers, and, to clap the climax, another fellow comes along and proposes to supply fuel gas to the citizens, gets a franchise, puts in pipe service, and our friend wakes up some fine morning to find that what the electric light fellow has left him in the shape of lighting has been captured by the fellow with the fuel gas plant, who puts in the incandescent gas burners.

Evidence is cropping up all around us that tends towards this change. We find manufacturers of fine clay goods now making carbons for electric lighting; we also find gas fixture manufacturers now making and selling electric wire of all kinds, besides other apparatus connected with the electrical field. Manufacturers of meters have not yet devised a meter for measuring electrical currents, but, perhaps, it would pay them to devote a portion of their time in studying one out.

As far as the present meter business is concerned, I think if this transformation of the gas business is brought about that the demand for gas meters would be quadrupled and the use of the larger sizes of meters would be made necessary, but if accuracy could be insured with a much smaller meter with quicker action, I think it would be better adapted for the purpose. Fuel gas, if it can be manufactured at a price by which it could be sold with profit at a lower or as low price as coal, would prove a larger field than all the kinds of lighting put together, and is certainly worth our while to investigate thoroughly. The owners of the smallest houses of our cities would become our patrons, and a small profit per 1,000′ would represent a wide margin when taking into consideration the large amount that would be consumed.

But is the fuel gas practical, and has there been sufficient progress made to date to warrant gas companies taking hold of it with any assurance of success?

In the first place, what assurance do we require? Do we want some one to come along and guarantee us a profit of 20 per cent. on our investment if we enter the field? If so, the patentees of the different processes might just as well negotiate with the shoemaker as with the gas company. I think all the assurance we want in the premises is, that with certain apparatus we can get certain results from a ton of coal (the kind of coal being specified), or that from a ton of coal we can get a certain amount of available deliverable heat units.

The balance we should be capable of working out ourselves, such as labor, leakage, cost of gas at consumer's meter, and such other data that we certainly should be more familiar with than anyone else.

Of course, the fuel gas will have to have an odor, and must be delivered at a proper pressure, and proper appliances for governing supply and insuring perfect safety will have to be calculated on; in fact, the gas man must try to improve on methods adopted, and do his best to hasten the day when solid fuel in our homes shall be no more—in other words, have got to take hold of the fuel gas business in its infancy, or it will get weaned away from us. Mr. McMillin, with others, has given us some figures on fuel gas which have been verified by practical tests; for instance, he gives us as his opinion that a mixed gas is more adapted for all-round purposes than either coal or water gas alone.

From experiments made, we find that from a ton of bituminous coal making a mixed gas, that we can realize as salable gas 63 or 64 per cent. of the total heat units in the original ton of coal, or about 17,000,000 heat units, besides a residue of heat sufficient to produce the steam for making the above amount.

Of this mixture, 20 per cent. is coal gas made in the ordinary way, which is the only objectionable feature the writer can see in the process. I am inclined to think that Mr. McMillin rather strained a point here in order not to alarm coal-gas men, or else to avoid a too radical change in the apparatus now in vogue for making coal gas.

By his statement, we find that in water gas for labor and repairs cost but seven cents per mile, while coal gas costs for the same items 15 cents per mile. Of course, the proportion of coal gas made by the old method is of more value in heat units than the water gas made by the new method; but what I wished to suggest was this, that if the whole process be made in the cupola, as water gas is now made, whether the results would be the same numbers or nearly so of heat units in amount of gas made with a large reduction in labor, seven cents, making the coal gas cost no more than the water gas for the item of labor repairs. If the mixture can be made in this manner, and I have some assurance that it can be done successfully, then I think it would pay any

company to abandon the use of the present style of gas benches and use the space now occupied by them with more improved apparatus rather than use them at a loss, simply because we have them on hand.

We have pictured an ideal burner for our homes in the forepart of this paper, and I cannot refrain from holding up to your view this fuel, which has no smoke, no dirt, no ashes, and entails to the housewife no extra labor, can be regulated automatically to one steady temperature, and does not require a workingman, after doing a hard day's work, to come home and find a ton of coal dumped on the front sidewalk which has to be wheeled or carried in before night comes on.

Now that we have seen an ideal street light, an ideal house light and an ideal fuel, we will endeavor to show you an ideal gas company, and we cannot do it in a more concise way than to say that an ideal gas company is one that keeps all these ideal commodities for sale at a reasonable price.

This may look visionary on my part to some of you, perhaps all of you, but, nevertheless, I feel that this is the place and time to talk over "our future prospects," and if this paper is the cause of anyone investigating the subjects spoken of or bringing forth discussion regarding the same, I shall feel I have not written in vain.

THE POLICY OF GAS COMPANIES AS TO INCANDESCENT ELECTRIC LIGHTING.[1]

BY F. W. DAY.

Mr. President and Gentlemen:—THE general inquiry for information is evidence enough of the importance of the subject. We hear on all sides the questions:

(1) What effect will the introduction of an incandescent electric plant have on our business?

(2) What amount of capital does it take to put in such a plant?

(3) Can they sell light as cheap as we, and make any money?

(4) Are gas companies any more favorably situated for furnishing electricity than anybody else?

At the meeting held in Dayton a year ago, you listened to two papers, one entitled "Gas and Electricity—Two Interests or One," in which the operation of the gas and electric light business, separately and collectively, was discussed. The second paper had for a subject, "Gas with Electricity," in which the results of a year's experience in running gas and an arc light plant collectively were given, accompanied with many practical suggestions of much value to those who had the introduction of an arc plant under consideration. In fact, the ground was so completely gone over that there is very little room left for saying anything new. However, the enormous sale of incandescent electric apparatus during the last year, together with the rapid improvement in the modes of generating and distributing the current, have added much that is of interest on the subject. We hear wonderful stories of a new system whereby the amount of necessary first investment in distribution plant is divided by 10, and at the same time the loss incident to distribution is reduced from 15 per cent. at a distance of one-half a mile to two and one-half per cent. and no consideration shown to distance whatever. Verily they sound like fairy tales. We might well ask "Where is it to stop?" It would seem that the limits in these directions had well nigh been reached.

It is, I believe, very generally conceded, that for some purposes the arc light is far superior to gas. It has been frequently stated that the introduction of arc lights is accompanied by an increased consumption of gas in the immediate neighborhood where the arc lights are used, which increase is directly traceable to the presence of the arc light. Will this be the case with the introduction of the incandescent lamps? I believe not. The popular idea that there were "millions" in the lighting business has given the incandescent promoters command of almost unlimited capital—and with what result? Two examples will suffice to show. The Edison Electric Manufacturing Co. claim to have at the present time 68 central station plants in operation, supplying current to over 500,000 lamps, and representing an investment of about $12,000,000—much the larger part of which has been thus invested during the last three years—with many large unfulfilled contracts on hand. In this country the first plant running on the alternating system was put in operation in 1885. At or near the beginning of 1887, the Westinghouse people began to place that form of incandescent apparatus on the market, and in less than eight months they had established 14 such plants, supplying current to 15,000 lamps, and representing a capital of about $350,000, with contracts amounting to nearly $125,000 on hand. Later information credits them with having, up to the present time, put into operation 85 plants, supplying current to 175,000 lamps, and representing an investment of about $5,000,000.

In view of these facts is it not safe to predict, that the same energy and push that has characterized the locating of these plants will not rest until every town in Ohio, in the business portion of which 500 lamps could be placed, has been afforded the opportunity of using them; and if they are not furnished by the gas companies therein located, they most surely will be by some one else.

Would a merchant be called enterprising that allowed a new article of merit, and in his line, and which he could have handled with profit, to be sold to a part of his best trade to almost the exclusion of his own goods—simply because he refused to put it on the market, when he could have sold it at a less price and at the same time made as large a per cent. on the capital invested as did the other man?

On the contrary, I think he would be called slow.

The skeptical will no doubt ask, "What has all this to do with us?"

Let us see.

(1) The introduction of an incandescent plant into the business district of a town means the loss of the gas consumption of at least a 5' burner for each incandescent lamp used.

(2) The cost of a plant would depend largely on whether the direct current three-wire or the alternating systems were used, and this, as well as cost of machinery, would depend on the circumstances under which the plant was to be operated, the distance the lamps were from the station, the difference in commercial efficiency of generating apparatus, all coming in for due consideration.

We will suppose that the system requiring the least capital is introduced.

We are told that the amount of investment, including land, buildings, steam plant and complete generating and distribution apparatus, erected and ready for use, would average $25 per lamp; adding 10 per cent. to this as a factor at safety, would make a 1,000-light plant cost $27,500.

The third question requires more in reply. We will take, for example, a plant located in a town, the business portion of which would use 1,000 16-candle lamps, with a 16 c. p. 5' gas selling at $1.50 per 1,000', taking four hours as the average daily usage, the total consumption displaced per month would be 1,000' × 5 × 4 × 30 = 600,000', which, at $1.50 per 1,000', equals $900, or an average of 90 cents per month per burner. Allowing for leakage of a little less than eight per cent., the net profit on the gas sold at that rate to pay 10 per cent. on the capital invested would be 55 cents per 1,000' or $330 per month of 30 days. This would be the net reduction of the profit accruing to the gas business resulting from the introduction of 1,000 incandescent lamps if current was supplied from 6 P. M. to 6 A. M.

Now suppose the lamps were furnished at the cost of a 5' tip, namely, 90 cents per month, the income from the 1,000 would be $900 per month. No meters being used, the charging consumers with the cost of renewals of lamps, the company guaranteeing them to last 800 hours, would have a tendency to limit the hours of use to those specified in the contract, but they would still burn them more than they did the gas jets, allowing 33 per cent. increase for this, and dividing the lamps and hours of use, thus:

600 lamps	from	6 to 10 P. M.,	4 hours	= 2,400 hours.
300 "	"	6 to 12 "	6 "	= 1,800 "
100 "	"	6 to 6 A. M.,	12 "	= 1,200 "
Total of 1,000 "				= 5,400 hours

per day, an average of 5.4 hours per lamp per day.

They would cost with a consumption of six pounds of coal per hour per horse-power, and an average efficiency of eight 16 c. p lamps per horse-power, coal at $2 per ton:

For fuel

125 horse-power 4 hours	= 125 × 4 × 6	= 1,500 pounds.
50 " " 2 "	= 50 × 2 × 6	= 600 "
12½ " " 12 "	= 12½ × 12 × 11	= 1,650 "
Coal used in banking retorting fires,		350 "
		4,100 pounds.

At 10 cents per 100 weight	$4.10
Water at 30 pounds per horse-power per hour = 22,500 pounds = 360' = 2,664 gallons at 50 cents per 1,000 gallons =	1.35
Proportion of superintendent's salary	2.00
Engineer and station man	3.00
Fireman	2.00
Day watchman	1.65
Lineman and helper	2.50
Repairs to engines, boilers and dynamos, at 5 per cent. on investment	1.50
Oil	1.00
Interest, insurance and depreciation at 16 per cent	12.25
Taxes	60
Making total daily expense of	$32.00

For average month $32 × 30½ = $976, increase being but $900, would make a net loss of $76 per month. If placed at 90 cents for those used until 10 o'clock, $1 00 for those used until 12 o'clock, $2.70 for those used until 6 A. M., which would be the cost of a 5' gas burned all night, the total increase would be $1,060 per month, less $976 expenses, would leave a net profit of $84 per 1,000, or $1,008 per annum, a little less than 3¾ per cent. on the capital invested. A plant under these circumstances would hardly be called a bonanza.

In cases where (as Mr. Wood suggested) the waste heats could be used to such an extent as to save 50 per cent. of the fuel, and the balance could be made up of coke breeze, costing one cent per

1. Read at the Fourth Annual Meeting of the Ohio Gas Light Association, Sandusky, O., March 21, 1888.

bushel to handle, the expense of firing would be reduced at least one-half, making the whole cost of production per day :

For fuel, 2,050 pounds, at one cent per bushel	$ .52
Other expenses	27.42
Total	$27.94

In round numbers $28, $28 × 30½ = $854 per one month. With income $1,060 and expenses $854 we have profit $206 × 12 = $2,472 or nearly 10 per cent. per annum on the capital, as estimated by the Westinghouse people.

By the operation of an arc plant in connection with the incandescent, some of the items of expense would be divided, making the net earnings considerably larger.

The cost as estimated here is no doubt larger than it would be placed at by the electrical engineers, but we had better err on the safe side.

The manufacture of a cheap fuel gas, made use of in gas engines, together with the advent of cheap and efficient storage batteries, or accumulators, would lower considerably the amount of first investment and at the same time cut down the cost of production.

However, it will not be long now until our energetic hosts will again be able to give us the benefit of their experience with their new venture, being now engaged in putting in an incandescent plant.

It would seem from the figures here given, that gas companies *are much more favorably* situated for furnishing both arc and incandescent lights, or electric current, than *anybody else*, and that they should pursue the policy of fortifying themselves in their present positions by obtaining authority so to do, if necessary, keep an eye on the public pulse and if they will have it, *give it them*. By so doing they would make a powerful ally of what *might* under some circumstances be a formidable foe. Failure to occupy a field of action in advance of others sometimes results in disaster.

ON THE HEATING EFFECTS OF ELECTRIC CURRENTS.

On March 19, 1884, Mr. W. H. Preece, F.R.S., submitted to the Royal Society a paper on the heating effects of electric currents, showing the strength of current necessary to fuse the fine platinum wire employed for protecting submarine cables from the ill effects of atmospheric electricity. The paper proved that the law that regulates the production of heat is one which can be expressed by the formula $C = a\,d^{3/2}$, "a" being a constant dependent on the metal used, and "d" the diameter of the wire. The current observed was that which heated the wire up to the point of self-luminosity (525° C.).

Since "cut-outs" of the same character as the cable lightning protector have become an essential feature of all electric lighting installations, to act as safety fuses when from accident or design an excess of current is allowed to pass through the conductor, it became most desirable to determine the current that would fuse wires of different diameters, and of different materials, so as to determine the coefficient, a, for all metals. The best material to use and the proper dimensions of the fusible wire to be employed for the protection of the electric light conductors would thus be easily deduced.

Mr. Preece obtained samples of wire of various metals (copper, aluminum, platinum, german silver, platinoid, iron, tin, tin lead alloy, and lead), and of various diameters from 0.004 inch up to 0.040 inch. It is convenient to take these measurements in thousandths of an inch (*mils*), for all our manufacturers and electric light engineers in the United States and the United Kingdom work to this gauge. The conversion of the values thus obtained into the metrical and more scientific system is very simple. The wire to be experimented upon was clamped between two small brass binding screws fixed upon a dry wooden stand.

The author pointed out in his previous paper how the cooling effects of the terminals or binding screws might vitiate the results, and how necessary it was to experiment on wires of sufficient length to prevent any error occurring from this cause. He used lengths of 6 inches to determine the constants for wires free from the cooling effect, but lengths of 1¼ inch with massive terminals to determine the constants for wires used in practice as "cut-outs."

The cooling effect of the terminals very seriously affects the efficiency of the "cut-outs" used in actual practice, and the larger the fusing wire and the terminals the more serious is the error introduced. On the other hand, the greater the lengths of wire used as a fuse the greater the resistance inserted, and the efficiency of the system itself may be reduced. Cut-outs, therefore, should be employed sparingly and with judgment, and the fusing wire should not be so short as to impair the fusing point.

When one considers the irregularities in drawing these fine wires to true cylinders, the difficulty in determining the current at the exact moment of fusion, and the variation in the specific resistance of the metals, Mr. Preece thinks the results must be considered very satisfactory in support of the law.

Three points of observation were taken:

1. The melting point of a small flake of shellac placed on the wire, which may be taken at 77° C.
2. The point of self-luminosity, 525° C. This was only determined roughly in air without the dark chamber he employed previously.
3. The fusing current.

A second series of experiments was made to determine the relative effect of the sudden application of powerful currents on wires of different materials (tin, platinum silver alloy, platinum foil, aluminum foil, silver foil, pure silver wire, zinc foil, copper wire, brass wire, hard drawn bright steel wire, and mercury), such as would occur if in practice a short circuit suddenly took place. An electromotive force of 100 volts was used, and there being no appreciable resistance in the external circuit but the wire, the latter was subjected to the blow of a momentary current of immense and immeasurable strength.

The conclusions derived from these experiments were that the best metal to use for small diameters was platinum, and for large wires tin. Platinum fuses in a wax-like kind of way without explosion or scattering of molten particles. Platinum has great advantages over other materials; it neither tarnishes nor deteriorates. It is easily soldered.

Tin behaves very much in the same way when its dimensions are large. But it is very questionable whether large wires should ever be used for fusible cut-outs. Owing to radiation the surface keeps cool and solid, while the centre is molten and liquid. It bursts with an explosion, and the incandescent particles are forced away radially in all directions with considerable energy.

Fusible cut-outs are effective but somewhat barbarous, and from the absence of any scientific inquiry into their character and judgment in their use, they have in the majority of instances become rather a source of danger than of safety.

A third series of experiments was made to determine the constant "a" when each wire was 6 inches long, and therefore free from any cooling effects of the terminals.

The value of the constant "a" for the different metals is therefore :

	Inches.		Centimeters.
Copper	11684.0	..	2886.0
Aluminum	7948.4	..	1964.0
Platinum	5258.0	..	1299.0
German silver	5203.7	..	1285.0
Platinoid	4860.7	..	1201.0
Iron	3190.9	..	788.0
Tin	1800.6	..	445.0
Alloys (lead and tin), 2 to 1	1455.5	..	359.5
Lead	1512.27	..	373.5

The values in the second column are obtained from those in the first by multiplying the latter by $\frac{1}{(2.54)^{3/2}} = 0.247$.

Since $C = a\,d^{3/2}$ gives the fusing current of any wire of a given diameter, d, inversely—

$$d = \left(\frac{C}{a}\right)^{2/3}$$

will give the diameter of the wire which will fuse with a given current C. Very useful tables can thus be calculated which would be of service to the electric light engineer.

[January 5th, 1888.—In all the experiments the results obtained on wires finer than those recorded, viz., those below 10 mils. were excluded, because it was found that they did not follow the law of the 3/2 power. In the discussion which followed the reading of the paper, Professor Ayrton pointed out that this must be so, and that it followed Mr. Box's researches of 1868 that the current required to maintain a fine wire of a given material at a given definite excess of temperature is approximately directly proportional simply to the thickness of the wire. This has been fully developed in a paper read before the Society of Telegraph Engineers and Electricians, November 24th, 1887 (*Journal*, Vol. 16, p. 539).]

DESIGNING ELECTRIC MOTORS.[1]

BY FREDERICK WALKER.

The electric motor has now become a recognized article of practical utility, and has graduated, as it were, from a mere toy to an important commercial factor. There are, in the market, motors *and* motors, but yet we find in practice that for each and every particular application there exists certain stringent conditions which render it necessary to design a special electric motor that will fulfill the requirements of the particular application, even if a certain modicum of the theoretical 90 per cent. of efficiency has to be sacrificed.

The writer, among many other instances, may quote as an example, the numerous experiments conducted by himself when

1. From the *Mechanical World*.

designing and carrying out the construction of the first two or three electric locomotives of the set that are at present running daily on the tramway between Stratford and Ilford, belonging to the Elieson Electric Locomotive Co. In this case the special requirements were a low speed and a short field magnet, and, of course, the weight had to be reduced as much as possible, the latter condition being a *sine qua non* where electrical traction is concerned. Before dealing with such experiments in detail it will be well to consider the best practical method of arriving at the proportions of the car case, and the proper winding of a motor to suit the exigencies of electrical traction.

Taking an ordinary tramway car, weighing 1¾ tons, carrying 40 passengers, the united weight of whom is 2 tons, and allowing 1½ tons for 60 accumulators with an electric motor and accessories, the total weight that has to be propelled along the tramway track, at the regulation rate of speed of 7 miles per hour, is 5¼ tons. Upon an ordinary level track, under favorable conditions, the mean tractive force required should be about 26 lbs. per ton; therefore, since the maximum speed is

$$\frac{7 \times 5{,}280}{60} = 616 \text{ ft. per minute,}$$

and the load is

$$5.25 \times 26 = 136.5 \text{ lbs.,}$$

and the actual horse-power absorbed during the run at this rate of speed is

$$\frac{136.5 \times 616}{33{,}000} = 2.5 \text{ h. p.,}$$

and, adding the loss due to friction of the speed, reducing gearing, &c., at a rate of 15 per cent., the total becomes 2.87 h.p.

When ascending a gradient of, say 1 in 80, the power absorbed is proportionately greater, for the tractive force becomes

$$\frac{2{,}240}{80} = 28 + 26 = 54 \text{ lbs. per ton,}$$

and the total power required to maintain the former speed of the car up the incline is

$$\frac{5.25 \times 54 \times 616}{33{,}000} = 5.2 \text{ h.p.,}$$

and, since 1 in 80 is a comparatively light gradient, it serves to illustrate the range of actual mechanical force that is required in order to drive an ordinary tramcar along a variable track. In designing the motor and gearing, there must not be a single pound weight of surplus material, as every pound of dead weight requires nearly 8 foot-pounds of energy in order to propel it at a speed rate of 7 miles per hour on a level road. Now, in order to overcome the *vis inertia* of the loaded car, that is, start it from a position of rest, requires an approximate tractive force of 78 lbs. per ton, or a total of 7.7 h.p., representing the necessary initial force required. Suppose that there exists upon the track no gradient steeper than 1 in 80, and the weight of the loaded car and its accessories is 5¼ tons, and that we have to provide a motor or motors wherewith to drive it at a speed of 7 miles per hour, the maximum power required is, as we have seen, 7.7 h.p., but to which we must add the power absorbed by the motor, and also by the gearing. If the latter be properly adapted it should absorb but 15 per cent., and the motor should at least possess 70 per cent. of efficiency when running at its critical speed. Now the maximum electrical horse-power that has to be exerted for about one minute, while overcoming the *inertia* of the car, is approximately 8,300 watts, and the discharging E. M. F. of the accumulators is about 1.98 volts, the available E. M. F. from the 60 cells is 118.8 volts, and the maximum current is 69 amperes. Upon this data, therefore, we may begin to calculate the dimensions of the motor, remembering, however, that although 70 per cent. is a low efficiency for an electric motor, and that it is possible to construct one to absorb about 9.5 per cent. of the electrical energy, it is only in very exceptional cases where the latter would be applied for the requirements of electrical traction. An ordinary tramcar wheel is 30 inches diameter, or 15 inches from the rail to the centre line of the axle. The floor of the car must not be raised above the centre line more than 16 inches, and allowing 4 inches for clearance at the bottom and top, the motor cannot exceed 22 inches in diameter over the pole-pieces. In practice, however, we should find that an armature 15 inches in diameter would perform the necessary work, and, assuming that we use bent wrought iron field magnets of the shape usually known as Siemens's, the iron core would be 1⅝ inch in thickness, and each magnet core 14 inches in length, and the width 10 inches, of course corresponding to the armature, which will be 10 inches in length over all when wound. Now we know that the initial and maximum running current, C^1, is 69 amperes, and that the initial E. M. F., E, at the terminals is 118.8 volts; therefore the resistance, r, of the motor will be deduced from $C^1 \times 1.35 = 93.15$, being the current, C, that will pass through the motor when it is absolutely stationary. The resistance, r, will be, therefore,

$$\frac{118.8}{93.15} = 1.2 \text{ ohms.}$$

Now, any coil or coils of wire revolving in a magnetic field must have a potential generated in it or them; therefore, as the motor in question is to run at a reasonable speed to suit the intermediate gearing, say 650 revolutions per minute, a counter-electromotive force, e, is set up in the wire tending to check the flow of current from the accumulators, because it is acting in an opposite direction. The counter-electromotive force, e, in this case will have a value of about 85 volts, and, therefore, from the above data we may estimate the theoretical efficiency of the motor.

The current absorbed when the critical speed is attained is

$$\frac{E - e}{r} = C,$$

and this represents the maximum efficiency when the motor is performing most work and absorbing least electrical energy. Substituting the known values in this equation we get

$$\frac{118.8 - 85}{1.2} = 28 \text{ amperes,}$$

so the values of the varying current in amperes are as follows:—

$C = 93.15$ amperes standing still.
$C^1 = 69.00$ " moving slowly.
$c = 28.00$ " critical speed.

Now the proportion of energy utilized as tractive force and the energy actually absorbed by the motor is represented by the fraction

$\frac{e}{E}$; or substituting the values,

$\frac{85}{118.8}$, or 71 per cent. efficiency.

I am of opinion that the counter-electromotive force, e, of a motor is analogous to the expansion of steam in a steam engine cylinder, with regard to its economical results, for we see at once that the most effective and economical electric motor would be one in which the values of the E and e were nearly equal. This would mean a high rate of speed per yard of armature conductor, and since in the present case such a speed is not admissible, the result could only be obtained by largely increasing the diameter of the armature. This is likewise impossible, because of the limited space occupied by the motor and gearing, and under any circumstances a motor possessing a high degree of efficiency is too heavy and cumbersome for application to tramway traction. Taking into consideration the enormous additional weight of a motor of 90 per cent. efficiency, and the power absorbed in transporting such a weight, it has been found more practicable to employ a lighter motor with a less commercial efficiency. There have been of late years several patents taken out, based upon Froment's bar armature, solely with a view to obviate what the inventors chose to consider a serious disadvantage, viz., counter-electromotive force. The efficiency of such a motor must, of course, depend upon the single statical pull of the field magnets upon each bar in succession; therefore the current absorbed must be enormous in proportion to the mechanical work done upon the spindle.

I have found in practice that the best armature core is one built up of a number of segments, forming a perfectly circular ring, each layer of which is carefully insulated by the interposition of sheets of paper soaked in shellac varnish, and the whole taped over ready for winding as a Gramme ring. The wire must be chosen of sufficient sectional area to carry the maximum current for a short time without becoming unduly heated, and the length of the armature conductor must also be proportionate to the counter-electromotive force, e, that is required, and the resistance between the brushes; or, to put the matter plainly, the resistance between two opposite segments of the commutator, is best when about 0.55 of the total resistance, r, which has been established by calculation. The commutator should be divided at least into 60 parts, and should possess a good bearing surface for the brushes, in this case at least 5 inches clear, for it must be borne in mind that the tangential contact of the brushes is exceedingly fine when the commutator is perfectly circular, and also that an electric motor, unlike a dynamo generator, receives the current upon the commutator suddenly, the greatest current, of course, passing when the motor is at rest, and is required to move. The end bearings should be long, so that the intervening film of oil shall not be driven out by centrifugal force when the motor is running, and also in order to distribute the pressure of the rotating spindle over as large a surface as possible. Every opportunity should be afforded for the free ingress

of air around the revolving armature, so that the temperature may be reduced as much as possible.

There are many methods that have been employed with more or less successful results of varying the speed of an electric motor when applied for the purpose of traction. Resistance coils are frequently arranged so that they may be interposed in the circuit by means of a multiple switch at will. This method is exceedingly wasteful, as the reduction of speed in the motor is accomplished by the absorption of a proportionate amount of the electrical energy in heating the resistance coils. Another method is to cut a number of accumulator cells out of the circuit, and so reduce the E. M. F. This is not practicable, because the accumulators are then unequally discharged, and there is a corresponding waste of energy during the process of recharging. I have found in practice that it is better to arrange a compound switch so that, in the case of a single motor, the field magnet connecsions could be varied at will. Where two or more motors are employed it is an easy matter to arrange a circuit, governed by a proper switch, so that the motors may be run singly, in series, multiple, or multiple series. An essential point in a motor for purposes of tramway traction, or for electric launches, is a simple method of reversing the motion. This may be done by means of a duplicate set of brushes, or by reversing the direction of the current around the field magnets; or special differential gearing may be interposed between the motor spindle and the work.

Without doubt the time is approaching when electrically propelled tramcars and boats will be no longer isolated cases, but will be among the common sights of every-day life upon every river and in every large town in the kingdom, and engineers will be as familiar with the electric motor, in theory and practice, as they are at present with the steam engine.

ALTERNATING *vs.* CONTINUOUS CURRENTS.[1]

BY M. M. M. SLATTERY.

A FEW days ago, when I had the honor of receiving an invitation to read a paper before this club to-night, relating to the alternating system in parallel arc, to be in reply to Mr. Leonard's paper, I felt, understanding Mr. Leonard's proclivities, that the usual stereotyped attack would be made upon a system which has alike elicited the admiration of those who have disinterestedly given the subject some thought, and the most rancorous feeling on the part of those whose business has been placed somewhat in the background by the rapid developments which have taken place in this comparatively new field of electric lighting. In a moment of unguarded enthusiasm I accepted the invitation. As some of you may know, I am practically engaged in the alternating branch of electric lighting, and my time is so much occupied therein as to almost entirely preclude me from having time to either write or read papers. I regret, therefore, that in this short paper I shall not be as comprehensive as I should wish, and will principally confine myself to replying to some of the salient points in Mr. Leonard's paper.

We are told that the following are the sum total of the vital factors in a general supply system of electric energy, viz.:

1st. Cost.
2d. Economy (efficiency and depreciation).
3d. Reliability.
4th. Safety to life.
5th. Variety and value of the possible sources of revenue.
6th. Effects upon existing property.

The factor of distance over which you have to transmit the electric energy is conspicuous by its absence, not being considered of sufficient importance to be enumerated in the list; we shall see presently of what value this factor is. Of course Mr. Leonard, as is customary with advocates of the low tension system, starts out with an explanation of the transcendent merits possessed by the three-wire system, and expresses in the usual terms the 66 per cent. saving over the two-wire system.

In the paper read by Mr. Leonard, elaborate tables of figures are given, into which I will not attempt to follow him in detail to-night. It would only weary you, and, as you are aware, if the premises are once granted, almost anything can be proved by figures. All I would say is, examine those figures yourselves, but do not assume that the data are correct.

It is a very ingenious rhetorical device to take the cost of the Edison system for distribution over a small area, and compare it with the cost of the induction system over a small area, and thus show that, taking price of converters into consideration, the Edison is the cheaper. This is avoiding the question. The chief claim made for the alternating system is that it can reach customers and supply a market that the low tension system never can.

Another point to which I would call your attention is this: Mr. Leonard assumes the cost of copper to be 16 cents per pound; he had to bring his estimates at all within bounds. Now, we all know that the price of copper is more like 25 cents than 16 cents. The variation in the price of copper affects the low tension system much more seriously than it does us—another point in favor of the induction system. It may be said, "Yes, but you have to use copper wire in your converters as well as your lines." True, but only to a limited extent, the cost of the converter being largely made up of the iron and the labor. The quantity of wire in a good converter is but small.

Another reason why I do not care to take up your time with a detailed discussion of these figures and tables is that the field has been pretty well covered by Mr. Stanley in a paper recently read by him in Boston, and also for the reason that Professor George Forbes, who is recognized as one of our best authorities, has said with regard to the theoretical economy of the three-wire system that "this may suit American financiers, but is not electrical engineering."

Mr. Leonard is not warranted in assuming a thing in order to enhance the value of his claims; he says we may look forward to improvements in the 100-volt incandescent lamp which will result in 30 per cent. reduction in the cost of conductors in the three-wire system. I have been engaged in the manufacture of incandescent lamps for some 12 years, and, as I have to follow the subject up closely, I trust I ought to know a little about the improvements which have been made in the past, and the possibilities ahead for the future, and I find that for the four years just past very little has been done towards improving, either the life, or the efficiency of incandescent lamps.

A so-called improvement by a well-known company, the Edison, has lately been trumpeted in every direction. Why, Swan has been making such a lamp in England for some five years, and so could this same company have made them if they only employed methods which are equally within the reach of all. The reason for this recent claim is obvious; it is an off-set to the large number of lamps per horse-power claimed for the induction system. With regard to the claim put forward on behalf of the Edison company of being able to obtain twelve 16 candle power lamps to the horse-power, I will not dispute it, but simply say that the gentleman who was for four years the mechanical engineer of the Edison Electric Light Company has, within the past six months, given sworn testimony in these words: "In the direct current central station system, the maximum which, to my knowledge, has so far been obtained, is between six and seven lamps to the horse-power."

Now, gentlemen, a 100-volt lamp, such as the Edison, could certainly be made which would run, say 12 to the horse-power, yes 15, or 20, but what would be the life of those lamps? In all probability, as far as our present knowledge goes, very brief. I prefer, in a case like this, to rely upon an absolute statement of fact rather than upon any promises or guarantees or possibilities.

The limit of voltage at which a lamp can be made so as to have a reasonable life has, it seems, been reached in its upward direction at about 110 volts. It was anticipated a few years ago that a high volt, small current lamp was the great desideratum. Scarcely any progress in that direction has, however, been made for some time, as I have just said, and the tendency, in fact, now appears to be the other way, *i. e.*, toward low resistance lamps—say 50 volts to 70.

The continuous current system is far more susceptible to heavier fluctuations than the alternating, owing to the total absence of automatic regulation in the former; and, when it is remembered that the light intensity of an incandescent lamp does not vary as the potential difference at its poles, but in a much greater ratio, it will be readily understood that the fluctuating system has a much more hurtful effect upon the delicate incandescent lamp than the non-fluctuating system. I am supported in this statement by not the opinion, but by facts deposed to by the gentleman referred to. He says: "The usual percentage of loss in the carrying wires of a direct current system is 15 per cent., and even with this heavy loss the carrying wires attain a stupendous weight. The practical result from the introduction of this loss in the main wires of the direct current system is, that when such a plant is running fully loaded, the E. M. F. at the dynamos, will be 15 per cent. higher than at the lamps; whereas, when only lightly loaded, difference in E. M. F. at the dynamos and lamps runs down to a much smaller figure; therefore, in order to maintain the lamps at a uniform brilliancy, the E. M. F. at the dynamos must be carefully watched and adjusted to suit the varying requirements of the load, as in the absence of such care the brilliancy of the lamps will fluctuate and give rise to serious lamp breakage. This regulation of the E. M. F. is accomplished partly by regulating the field magnets of the machine and by the introduction of artificial resistance in the main carrying conductors. The attention to secure these results is expensive, and the devices for accomplishing them very costly.

There is another matter in connection with central station arrangements which, it seems to me, disposes of the question of the relative commercial merits of the two systems in a conclusive manner, and that is this: The advocates of the low tension systems admit that as far as actual wire goes, the 1000-volt distribution is more economical than is the 100 or 200-volt—that is a pal-

1. Read before the Chicago Electric Club, March 19, 1888. The second of a series of papers upon the subject, "The Continuous Current *vs.* The Alternating Current," before the club.

pable matter. But, say they, in addition to the danger and other objectionable features of your plan, the cost of your converters is so great as to neutralize whatever advantages you may have in this way. Without going into that point for the moment, it will be seen that the converter itself costs no more whether the current supplying it comes from 1000 or 10,000 feet away; that being so, the difficulty which stares the Edison system in the face is the practical necessity of picking out for their central station about the most expensive piece of real estate in the district to be lighted. They must be near the centre. They say so themselves. On the other hand, with the high tension system, you may have your central station in the outskirts of the town on cheap land, perhaps on a canal bank or railway siding, so as to unload your coal direct into your boiler room, which may itself save many hundred dollars per annum, while the extra length of the comparatively small conductors would be but a bagatelle compared with the real estate investment in the centre of the town. That I am not speaking off the book in this matter will be seen when I quote a passage from a document issued by the Edison company, entitled "Information to Agents," and relating to the desirability of centrally locating the station. It is as follows:

"NOTE: In a given district to be lighted, the best conditions of economy in street installation are fulfilled when the station is located in the centre of the district. If the station is moved one-quarter of a mile away from such centre the cost will be about doubled. If the station is moved one-half mile away from centre, the cost will be about quadrupled. * * * there need be no hesitation in locating it in the most central locality. A few hundred dollars' increase in cost of lot will often save thousands in cost of street installation."

Now, as to the lamp, the reasons for the prominence which a 50-volt lamp is at present acquiring are four-fold, namely, cheapness in manufacture, efficiency, reliability, and that while it is the lowest limit in volts that we should allow ourselves (for distributing reasons) it exactly suits the most efficient construction of converter.

The fewer the number of turns of wire in a converter the better, with proper limits; and, as in a 50-volt converter we have only half the number of turns that we should have in a 100-volt, the advantages of a 50-volt lamp for our purpose will be apparent; the fact also is that, while the manufacture of the 100 and 110-volt lamp has received the greatest attention by manufacturers for obvious distributing reasons, the 50-volt lamp has received comparatively little notice, not being recognized as a factor in a general system of distribution.

The Fort Wayne Jenney Company is now making a 40 watt 16 candle power 50-volt lamp. This lamp could just as well have been made long before this, but there was no such demand for it as now exists. If such improvements as Mr. Leonard predicts for the 100-volt lamps are likely to take place and the ratio of the present efficiency of the 100 and the 50-volt lamp holds good, we might look forward to a corresponding increase of efficiency which would enable us to reduce the cost of our converters in nearly the same proportion; that is to say, the cost of a 40 lamp converter would be very little more than for the present 25 light. There would also be the proportional saving in the cost of interior wiring.

Much has been said and written by the opponents of the induction system about the respective first cost of an induction installation and a low tension continuous current installation, viz.: that the low tension is cheaper for very short distances. This sounds very much like a man who had a continually growing business and required an engine, saying that a small engine was cheaper for him than a larger one, because the smaller engine just then met his requirements; after a little time he finds it necessary to dispose of his small engine at a considerable discount for a larger one that will be more adequate to his growing needs. Why not put in at the first that system which will meet any and every illuminating requirement for all time, both at points near to and remote from the source of generation.

I do not know whence the information has been derived, but the theory does exist that with the reduction of the load in the multiple arc induction system there is not a proportional reduction of the energy supplied to the circuit, and that consequently the loss of energy in the line does not decrease proportionately with the load. While this theory would and does apply to a series system of transformers it does not apply to the multiple arc induction system, the latter standing in the same relation with regard to the energy supplied to each circuit as the low tension multiple arc. Upon another occasion I trust to have an opportunity for bringing forward mathematical deductions and power curves incontestibly proving this fact.

No doubt a system cannot be considered a reliable one unless you are able to multiple arc your dynamos; well, we are able to do this. It used to be regarded as difficult; but, with a great many of these apparent difficulties, we need only to understand their nature in order to overcome them, and although at the present moment we cannot couple as many together as we should wish, I venture to say that by the time such necessity arises we should be ready to meet it. It is stated that we cannot multiple arc dynamos economically, as occasionally one dynamo will shift the load and the other dynamo not only will take it, but will try to drive the other as a motor. In an incomplete system this is just what takes place, but in a complete system when any such irregularity occurs, a device is brought into operation that regulates the speed of the engine when any variation therein is inclined to take place, thus maintaining the speed of all the dynamos coupled in multiple, and their potentials uniform, and, consequently, an economically working system.

A good deal has been said from time to time as to the dangers of the induction system, and notwithstanding the repeated exclamations and statements of those who are acquainted with alternating currents and their use, yet only a week or two ago Mr. Leonard in his paper read before this club attempted to resuscitate this scare, which we supposed had been forgotten. Professor Elihu Thomson has publicly stated that he has taken a 1800-volt alternating current without serious inconvenience. I have myself, as have several of my friends, taken 1000 volts, and in all the cases with which I am acquainted nothing more than some temporary discomfort followed. The most serious case of which I ever heard was that mentioned by Mr. Carpenter Smith, at the Boston convention. In that case the man was not permanently injured, although under the influence of the current for quite a considerable time. Although I would not go so far as to recommend the use of the 1000-volt current as a morning beverage, yet it is absurd to let the impression go abroad that it is necessarily or even probably fatal. We recognize the fact that an electric current of 200 volts is less dangerous than one of 1000 volts; of course, we know that. Does it, however, follow that we shall throw to the winds every advantage that this higher pressure gives us? Because a buggy is less dangerous than a locomotive, do we therefore abandon the railroads? Because an arc light system requires more pressure than the low tension are we therefore to abolish every arc light in the country? These questions answer themselves. So in time will the other, and "those who came to scoff remained to pray."

As evidence of how safely we can work with the induction system, we find that there is nothing to prevent us placing our lamps upon existing gas fixtures, unless it be ignorance, or not employing the proper precautions to render the work absolutely safe. It is suggested by some that in order to prevent the high tension primary current being dangerous to life, in the event of a leak between the primary and secondary coils taking place, to ground the secondary; that if a leak took place from the high tension circuit to the low tension circuit, and there happened to be a ground somewhere else on the primary circuit, no harm whatever could occur to a person taking hold of the terminal of an incandescent lamp, and at the same time touching a gas fixture. While this arrangement makes the use of the lamps by the customers absolutely safe, it subjects the entire system to a strain on the insulation, which I don't think is quite wise, and, instead of grounding the secondary, I think the better plan would be to ground a sheathing of metal, interposed between and carefully insulated from the primary and secondary. So far as safety to life is concerned, this is just as good, but has the recommendation of not subjecting the insulation throughout the system to any strain whatever, and has been used for some time with satisfactory results in the converters made by the Fort Wayne Jenney Electric Light Company.

A charge laid at the door of the induction system is that of unreliableness, and a few small break downs which have occurred are exaggerated to a considerable extent by those interested in other systems. Such matters are liable to occur in all new installations, the Edison not excepted. They are simply indiscretions, errors of youth, and not faults of the system as such. In a very short time the experience we have gained in this respect will bear due fruit, and it will be found that the induction system will be just as reliable as the continuous system. In the absence of gross carelessness there is no reason to the contrary, and, indeed, down to the present time accidents have been rare.

With regard to an alternating current dynamo of 1,000 volts being more liable to burn out than a low tension continuous current dynamo of 110 volts, and that the depreciation of the latter is less than the former, this seems to me to be nonsense. Understanding the nature of the work that a dynamo has to do, and with proper experience in construction, there should exist no reasonable doubt about making one dynamo to work as reliably as the other. This is purely a mechanical matter and the ingenuity of our mechanics is equal to any such emergency as that, and, as to depreciation, I venture to say, in fact, I know, that the armature of an alternate current dynamo of the kind I have had any experience with at full load, does not arrive at anything like the temperature a low tension Edison dynamo does under the same conditions, and we all know what high temperature in a wire has to do with the deterioration of its insulation. Furthermore, by reason of the small quantity of wire necessary in the armature of the alternate current dynamo, we can afford to occupy more space and thereby have less crowding of the wire; thus we have an opportunity of increasing our insulation in proportion to the E. M. F. required, and yet keep within the limits of great compactness. For instance, in an 800-light machine made by the

Fort Wayne Jenney Electric Light Company, there are only 20 pounds of wire on the armature.

There has been some little uncertainty about the action of converters in respect to the fuses inclosed in the converter box frequently and mysteriously melting. This, however, I find is attributable to the temperature of the converter at full load not being calculated as a factor with the current for the melting point of the fuse, and I think it will be much better for us to be satisfied with an external double pole fuse at the point of junction of the primary coil with the primary line, and a double pole fuse on the secondary circuit as close to the converter as possible; this arrangement thoroughly protects the system, and a possibility of the failure of the converter becomes a very remote one.

It is said that the operating of motors by alternating currents is not a success. Well, it may be admitted that at the present time the commercial operation of alternate current motors has not attained very large proportions, but who is presumptuous enough to say that, when the present systems of alternate current supply are as old as the continuous, there shall not be as many and as satisfactory motors running on alternate currents as on continuous? Is it for any gentleman connected with the Edison company to stem the tide of invention, to say that the acme of perfection is reached in the triune system of that august body, and to thunder forth electrical excommunication on all heretical expounders of the faith? I trow not. Alternate current motors have been made which have in them the elements of success, and the subject is daily attracting more and more attention from some of our most talented workers in that direction, both practical and theoretical, as examples of which I may mention the valuable papers read quite recently, by Dr. Louis Duncan, before the American Institute of Electrical Engineers, and the earlier one read some months ago by Professor Elihu Thomson, with which no doubt most of you are familiar. The mere fact that motors will work with an alternate current is, of course, well known. The difficulties have been in the regulation. But a difficulty, gentlemen, is merely a thing to be overcome. That is what the difficulties are for. These will be overcome, as have so many others in the grand field of electrical progress. Why, I remember hearing Dr. Werner Siemens say with his own lips that it was hopeless to expect to make a dynamo with a higher efficiency than 50 per cent. He lived to see himself mistaken, and perhaps others may do the same. "Not ten years ago the divisibility of the electric light," as it was called, was ridiculed as the chimera of an enthusiast's overheated imagination, and, nevertheless, where are we to-day?

The objection to the induction system on this motor question is based on the assumption that it is a desirable thing to operate motors on the same circuit as lights. Now, although at first sight this would seem to be the case, and although I am not prepared with any formal objections to that course, yet I do know of one company that has been running motors on the same circuit as lights, but is now running a separate motor circuit instead, in addition to its lighting circuit. So that there is such a difference of opinion on the question that it cannot be fairly disposed of by any *ex-cathedra* utterances of the advocates of any particular system.

One curious fact, which I think is not very generally known, though the information is public property, would seem to show that the Edison company does not regard the alternating systems as such insignificant opponents as it would have us believe. The advocates of the Edison system profess to regard all these induction high tension systems as inferior to their own, and as almost beneath contempt, yet, singularly enough, I find that twelve months or more ago the Edison Electric Light Company, of New York, thought enough of one of these systems—a European one, the Zipernowski—to acquire the exclusive rights in North America to use all the patents on that system, and to obtain certain privileges with regard to those patents. To say the least, it is strange that a company should be willing to negotiate for so worthless a system as they pretend it is. Does it not rather show that they are more frightened than they say, and are providing for themselves a *locus penitentiæ?* I think it does.

It may be considered that my remarks sound like a direct attack upon the Edison company's system, but I have frankly admitted wherein the induction system is weak, and only claim such advantages for the latter as are warranted by fact, and when we know of cases where, after large installations have been put in and paid for, such, for example, as that of Tyrone, Pa., the investors found upon careful consideration of the question, that they could make more money by setting aside their original investment and changing over from low tension continuous (three wires at that) to high tension induction, that I have not spoken too strongly. But, gentlemen, whatever I or anybody else may say in favor of one system and in condemnation of the other system, will, from a commercial point of view, affect the subject in dispute very little, and we may rest assured of one thing, that the public at large, whose business it is to study these questions, have discrimination enough and practical knowledge sufficient to enable them to make a wise selection. The respective systems, low tension continuous and high tension induction, are now before the public, and the ascertaining of their respective values is within the reach of those who desire to know them; they will perceive that claiming that a thing cannot be done does not settle the question, for they will see it being done, and the great question of the public will be what does this cost? What profit can I make upon my investment? Be confident that the public will not go far wrong when the information it seeks is placed within its easy reach.

COMPARATIVE VALUE OF THE CONVERTER AND CONTINUOUS CURRENT SYSTEMS OF ELECTRICAL DISTRIBUTION.[1]

BY E. P. WARNER.

UPON signifying my willingness to take part in the present discussion, it was with the distinct understanding that it should be a comparison of direct systems of distribution with converter systems, and embrace any and all systems, applicable to central station work. When the card announcing the programme so far as complete appeared, I was surprised to find the matter to be discussed very indefinitely stated. It seemed, however, to be settled by general consent of the members of the club that the discussion should take the form of a comparison as to value of the low tension continuous current systems with the high tension converter systems of electrical distribution. This reminds me of the numerous discussions of late, regarding the relative value of the high speed, high pressure steam engines, as compared with one of slow speed and low pressure; and viewing the matter as I do from a strictly non-partisan standpoint, it seems to me that the conclusion arrived at will be about the same, that is that each of the systems, as each of the engines, has its particular advantages under certain conditions.

Having followed somewhat closely the progress made in the development of the systems under consideration, I have come to consider the low tension continuous current systems as well suited in every way for distribution over a certain area from a central point, its extent being limited principally by the cost of conductors, and the loss of electrical energy in overcoming their resistance, while the high tension converter systems have appeared to possess certain characteristics that particularly fitted them for long-distance distribution, and that seemed their legitimate field of use. I do not propose to-night to employ either mathematical or geometrical demonstration, but to briefly go over the points in the two kinds of systems that seem to me to furnish a basis for comparison.

In H. Ward Leonard's paper, read before the Chicago Electric club on March 5th, a brief enumeration of the vital points in a supply system is given, which without doubt covers the ground pretty effectually, despite the charge made that he has neglected the matter of distance.

The main features of a low tension system such as the three-wire, are so well understood, and the means for accurate determination of cost, efficiency, etc., are so simple that I will not take up your time in going over them, but say that the statements made by Mr. Leonard regarding the three-wire Edison system are in the main correct so far as my experience goes.

Now for the converter systems. The question might be asked here "Why do we convert?" In answering the question the advocates of such systems are, as a rule, not at a loss for reasons, and put forward claims for the converter of so startling a nature that I can not help the thought that their wishes lead their judgment.

A recently published table of determinations of efficiency of converters under various loads, the result of calorimeter tests by Professor Ayrton, shows a very low efficiency under light load—a result to my mind very naturally to be expected. We know that in the nearest approach to the ideal dynamo that we are able to produce, the showing in efficiency under light load is not all that could be wished, and I think that to a certain extent the working conditions of a converter and dynamo are similar, and many of the troubles encountered in dynamos are met with in the converter; therefore, when we take into consideration the number of converters usually employed in an installation of only moderate size the matter becomes one of great importance.

Before proceeding to a consideration of these troubles, it would perhaps be well to mention briefly some of the objects sought in the construction of converters. They are, reduction of length of wire, and number of turns, also the weight and cost of all material used with a high general efficiency under all conditions of service.

The showing has been made that it is not economical to work converters with a high induction, and this fact stands as a bar to progress in the direction of reduction of material. Careful lamination and ventilation of pure, well annealed iron do not to any marked extent improve its storage capacity, and until we find an iron differing greatly in molecular structure from any at present in use we shall probably be without a remedy.

---

1. Read before the Chicago Electric Club, April 2, 1888. The third of a series of papers upon the subject "The Continuous Current *vs.* The Alternating Current," before the club.

I do not think the statement fair as made by William Stanley, Jr., at the conclusion of a paper read before the American Institute of Electrical Engineers, that to alternating or similar currents iron offers true storage capacity for all values of magnetization below the saturation point. It seems to me calculated to lead the student astray regarding the economical use of iron for this purpose. He would very naturally take it that so long as he did not pass the saturation point he would be getting a fair return, when as a matter of fact, he must stop far short of saturation, or suffer serious losses from a variety of causes. A large quantity of iron in proportion to wire is therefore a necessity in a converter designed for high efficiency, as the magnetization should at no time reach too high a point.

Another reason for working at a low induction is hysteresis, or molecular friction of the iron core. It has probably occurred to many of the members present that the heating of iron while undergoing rapid reversals of magnetizations could not in all instances be attributable to Foucault currents; also that the heat increased more rapidly than the intensity of magnetization; and again that the heat increased with a decrease in time between complete reversals.

Now, in the case of a converter any heating of the iron means a loss of electrical energy, and it is only by carefully restricting the degree of magnetism of the core, fine lamination, and good ventilation, that excessive heating can be prevented. It seems to be impossible to entirely prevent this loss.

The requirements for self-regulation of a converter are in practice such as to call for a sacrifice in efficiency in order to secure regulation. This loss is said to be small in certain forms of converters, but it goes nevertheless to make up the sum total.

To quote from an article on "Electrical Distribution by means of Transformers," by J. K. D. MacKenzie, published in the *Western Electrician* of March 10th: "The question of mutual induction in superimposed layers of wire one with another is of importance, and it is easy to see that since each wire through which an alternating current is flowing serves to induce a current in an opposite direction in the one next to it, which acts against it and against the third or succeeding one, and so on throughout the series, a loss is bound to result."

In considering this point it has occurred to me that this loss must be greater where very high electromotive force is employed in the primary, owing to the greater number of turns of wire employed in construction. I will make use of the words of M. M. M. Slattery, in a discussion which followed a paper read by him at our last meeting: "You are familiar with the alternating current type and you are aware that the greater the number of convolutions of wire, the greater the reactive effect. The same law holds good to a very much higher degree in the operation of the converter, and that is why we keep the number of convolutions of wire in the converter as low as possible, that the ideal converter, as the ideal dynamo, would therefore have but a single turn of wire." We see that in this, the electricians who seek to annihilate distance by the use of small conductors and high E. M. F. meet with a serious obstruction.

In the matter of distribution it strikes me that the size and location of converters must greatly affect the results. In the case of an installation of say 500 lights, it has been the practice for some time past to connect the secondaries of several converters in multiple arc to one pair of feeders that supplied the lamps. A rather unexpected trouble has resulted from this method of connecting. Should one of the converters of a group give out at a time when the number of lamps in service exceeds the capacity of the remaining converters, the fuses of these converters will blow out in rapid succession, and all the lights be extinguished. The remedy for this is said to be running separate local circuits for each converter, and at first sight this looks to be unobjectionable, but when we come to the cost of an installation for wire and labor, we can not fail to see that in nearly all cases the expense of running separate local circuits, would considerably exceed that of a single circuit. We can not buy several small insulated wires equaling in conductivity a larger wire at the same price.

Now, as to the dangers to life and property from the alternating converter system, it can not be held that the dangers are no greater than with the low tension system, whether alternating or continuous. Admitting that the safeguard to consumers provided by grounding one side of the secondary or local circuit is perfect, there is still considerable danger from the exposed overhead wire. When we take into consideration the great number of telephone, telegraph and other wires threading the streets of many of our cities, and the frequency with which crosses occur between the wires of the different systems, it becomes a pertinent question whether it will be found possible in practice to provide against accidents of such nature and frequency as to seriously detract from the value of a system. For this reason it may be found inadvisable to raise the E. M. F. above 1,000 volts, or even so high. While it is undoubtedly a fact that a number of persons have taken the shock from an alternating current of 1,000 volts and lived to tell of it, there are many people to whom it would be extremely hurtful, if not fatal. The danger of fire in buildings where the primary wires of a 1,000-volt alternating system are permitted to be placed, is beyond question much greater than with a continuous current system of 200 volts. Again, a cross between a telephone wire and the primary of the alternating system would be almost sure to burn the instrument at the subscriber's station, and might set fire to the building. One thing that increases the danger from this source is the fact—admitted by users—that it is practically impossible to so perfectly insulate the wire that no escape shall take place.

It has been claimed by several writers that if the primary wires of an alternating system endanger a building, so do the wires of an arc light circuit, where the E. M. F. may be as high as 3,000 volts. This is true to an extent, and we all know the precautions that have been deemed necessary by insurance people. But let us look at this matter a moment. In an arc lighting system it is not often that we find 25 lamps in a single building, which number would be required to bring the E. M. F. up to 1,000 volts, and this would only be found from the point where the two wires entered the building up to the first lamp on either side, gradually decreasing as the centre lamp is approached. The number of arc lamps in use in a building would therefore determine the danger. I think that in actual commercial lighting the average number of lamps to a building will be found far below 25; whereas with the alternating 1,000-volt system every building entered by the primary wires will be subjected to an even greater danger than it would be from an arc circuit furnishing 25 lamps.

Now to compare the high tension alternating systems with the low tension systems in the matter of insulation. Commencing at the dynamos we find that a much higher insulation is necessary on high than on low tension machines, and leaving out of the question the increased cost for insulating material, it is apparent that much greater care must be taken of the high tension armature in the matter of cleanliness, than of the low tension; also that a comparatively slight deterioration of the insulation of the high tension armature will entail serious loss of energy; and where an E. M. F. of 3,000 volts is maintained, this deterioration and loss may amount to a very considerable percentage of the total energy without resulting in the destruction of the armature. To this the advocates of high tension will answer—we will instruct our dynamo tenders to keep things clean, and the insulation will not deteriorate. Many of you no doubt know from experience how instructions instruct, and how frequently the insulation, which is advertised not to, proceeds to deteriorate.

The insulation of the primary wires of a high tension system from each other is a matter of far more importance than that of the armature wire, and in the case of overhead wires, it is found quite difficult and expensive to maintain the insulation at such a point that there shall be no appreciable loss of energy occasioned by leakage. When we consider the number of supports that must be provided for the primary wires, and the average number of converters with, perhaps, their secondaries grounded on one side that offer channels for escape, it is not to be wondered at that grounds are more the rule than the exception. Just here a grave objection to the use of very high E. M. F. comes in; it is, in plain words, that with a given insulation resistance, the higher the E. M. F. the greater the percentage of loss resulting. Suppose, for the sake of illustration, that insulation resistance between the mains of a 2,000 alternating system is 1,000 ohms, the loss would be 4,000 watts, or 5.36 electrical horse-power; while in the case of a 200-volt system—insulation resistance being the same—the loss would be 40 watts, about 1-17 of an electrical horse-power. The ratio of loss between the two systems, due to defective insulation, would therefore be as 1 : 100. This is a matter that the electrical engineer can not afford to neglect in estimating the general efficiency of a system.

To return to the safety devices and look at them with reference to their effect upon the insulation of a high tension alternating converter system, it has been admitted by an advocate of these systems in the course of this discussion that the practice of grounding one side of the local circuits throughout the systems subjected the insulation of the primary to increased strain, and was for that reason inadvisable. Let us see if it does not do more than this. We will suppose that there is a fair average insulation resistance between the primary and secondary wires of all the converters, also between the primary wires and ground. Now, whatever this may be, the result of grounding the local circuits will be to offer their conjoint resistance to ground, and in the case of a large number of converters so joined, the loss can hardly fail to be very considerable.

Another safety device, the invention of Mr. Kent, I believe, consisted of a metal plate or cover placed between the primary and secondary wires of a converter, but carefully insulated therefrom, and connected to ground. This safety device has the defect that it is purely local to the converter, and does not provide any safeguard from danger arising from crosses between the primary and secondary wires outside of the converter. It is common practice to carry both sets of wires upon the same poles, and any safety device that does not cover this point, can not be said to be perfect. Again, I hardly see how the metal shield can be made to completely envelop the primary or secondary without interfering with the action of the converter to some extent. This, however, is a matter upon which I can not speak from personal experience.

Regarding the efficiency of alternating generators as compared with continuous, it appears to be pretty generally conceded that they are about on equal footing; but in the matter of weight for a given capacity there is—unless very recent improvements have made a change—a slight difference in favor of the continuous machine. Part of this is probably due to the fact that the alternations in a continuous current armature do not take place so rapidly or frequently, and less iron can therefore be used in proportion to wire.

Theoretically there should be no trouble in operating alternating current dynamos connected in multiple arc, provided their reversals take place synchronically. Where they are driven by separate engines it is hard to see how this can be brought about.

I have not touched upon the matter of deterioration of the alternating converter system, as the time at my command did not permit me to obtain sufficient data to prove of use. Placing the wires in a high tension alternating system underground we must expect to encounter much more trouble from retardation than would be the case with high tension currents if continuous. It is possible to overcome this to a great extent by a proper disposal of the mains with relation to each other, and any iron that may lie within easy reach. But perfection in this would surely add to the cost of a plant.

During the progress of this discussion the assertion has been made that it was not good policy to put in a small plant and increase with the demands of business, and the advice given to put in a plant large enough to meet the expected increase; in answer I would say: It is a well-established fact that the maximum efficiency in operation of all steam engines is exhibited when doing full duty, and it has frequently been demonstrated that in cases where the increasing business of a manufacturer called for increased power, it would pay him better to put in several engines, increasing in power by steps as increased business demanded, even if the old engines were given away, than to put in a very large engine at the outset with the expectation that the business would soon grow up to it.

I can not help feeling that the use of converters in a system of electrical distribution is in a certain sense a step back, and is like introducing belting or gearing in mechanical work where direct application would be the wiser and more economical course. We see in modern machinery so many evidences of the truth and force of this remark that I am led to ask again, why convert?

In conclusion, it appears to be impracticable to supply any particular system in all cases, and an impartial consideration of local conditions with the general character of the distribution to be effected should guide the engineer in his choice. The matter is one that should not be lightly decided, and I am hopeful that this discussion may prove fruitful.

CORRESPONDENCE.

NEW YORK AND VICINITY.

Overhead Wires and Street Accidents.—Asperities in the Board of Electrical Control.—Annual Election of the Electric Club.—The Forthcoming Annual Meeting of the Institute of Electrical Engineers.—The Electric Railway at Asbury Park.—An Electrical Manufactory to locate at Rahway, N. J.—Electric Lighting and Politics at Red Bank, N. J.—A New Signal Service Cable.—The Legislature and Western Union Taxes.

THE writers of the daily press are beginning to learn that the electric wires are not responsible for all the dangers of New York streets, and have recently given much attention to careless driving, by which people are killed or injured nearly every day. Attention was directed three years ago through the columns of the ELECTRICIAN AND ELECTRICAL ENGINEER not only to the accidents at street crossings, but those arising from falling signs whenever there was a heavy gale. The prediction was also made that there would be more wires overhead after the time set by law for their final burial, than there were when the act was passed. The actual condition of affairs is probably worse now than at any previous time, as no arc lighting wires have been put underground, while they have been permitted to deteriorate where originally placed, until accidents have become alarmingly frequent. The latest victim was Mayer Streiffer, a young Jewish peddler, who was killed April 15th by contact with a "dead" wire which lay across an electric light conductor, and dangled near a pole close to the sidewalk, on East Broadway.

The difficulty experienced in coercing the companies to bury their wires, crops out in the proceedings of the board of electrical control. The snow and frosts of winter have not eradicated the asperities of discussion, in which his honor Mayor Hewitt and Commissioner Gibbens take part. At the first meeting held this spring Mr. Gibbens made the Mayor angry by remarking that the latter had failed to apply the remedial legislation provided for in the law in case the companies refused to take down the poles and wires and place the latter in the conduits provided for them.

"That is a statement that is absolutely untrue," exclaimed the Mayor.

"I reiterate the statement," remarked Mr. Gibbens.

"And I say it is not true," retorted the Mayor.

"The Mayor of the city has refused to order the Bureau of Incumbrances in the Department of Public Works to take down the poles and wires"—this from Mr. Gibbens.

"The Mayor of the city has done no such thing"—this from Mr. Hewitt—"and if he has refused to enforce the law why don't you, as a good citizen, impeach him?"

"I am willing to impeach him," replied Mr. Gibbens.

The board, after some further wrangling between Mr. Gibbens and the Mayor, ordered the contracting company to go on with the incomplete work of last year, beginning with the first week in May. The plans for new work were referred to the engineer of the board.

The election of officers at the Electric Club took place on April 19th and resulted in the unanimous choice of the following gentlemen: president, Henry C. Davis; vice-presidents, E. T. Gilliland, Geo. W. Hebard, O. E. Madden and George L. Beetle; secretary, Charles W. Price; treasurer, Willard L. Candee. The board of managers consists of Theodore N. Vail, George B. Coggeshall, Henry D. Stanley, M. W. Goodyear, Cyrus O. Baker, Jr., J. N. Keller, John C. Tomlinson, Charles W. Gould, Charles W. Spear, A. H. Patterson, H. L. Storke, H. A. Reed and John A. Seely. Committee on membership, Henry Hine, George Worthington, George T. Manson, Henry D. Lyman and Lieut. F. W. Toppan. After the election dinner was served, and a report of the affairs of the club was made by president Davis.

The annual meeting and election of the American Institute of Electrical Engineers will be held at 127 East 23d street on Tuesday evening, May 15th, followed by a general meeting for the reading and discussion of papers, on Wednesday, May 16th. The growth of the business and literary work of the Institute has made it necessary to secure suitable quarters for the accommodation of its library and files. The question of an up-town or down-town location has been settled, at least temporarily, by the leasing of a commodious room in Temple Court, 5 Beekman street. It will be occupied by the secretary, and utilized for council and committee meetings, while the monthly meetings of the Institute will be held as heretofore at the house of the American Society of Civil Engineers.

The Seashore Electric Railroad at Asbury Park, N. J., is encountering renewed difficulties in its preparations for extending its line toward Ocean Beach. In order to secure a right of way, a lot of poles were dumped on Main street, but the business men along the route have prevented their being planted until after a hearing before the commissioners.

Another important electrical industry is reported as being about to locate in New Jersey. The Forest Park Association at Rahway has sold quite a large block of land to a company which is to manufacture the Johnson electric service apparatus. The use of this system for the regulation of temperature in public and private buildings, is rapidly extending in the eastern states, and its operation is so perfect that every new installation leads to an increased demand.

The question of street lighting has entered into local politics at Red Bank, N. J., where the present board of commissioners granted the privilege to the electric light company, which will begin its service this month. The gas company claims that its contract for public lighting does not expire until August 1st, and that consequently the people will be obliged to pay for both gas and electricity until that date. This knowledge has built up an opposition party to the present board, and it is expected to be an important factor at the election May 1st.

General Greely, chief of the signal service, has contracted for the laying of a new cable from Woods Holl, Mass., via the Pasque and Naushon Islands to Vineyard Haven, Martha's Vineyard.

Unusual interest has been recently directed toward the doings of the lobby at Albany. Editor John I. Platt, of Poughkeepsie, has attracted attention to himself by reason of his introduction of a bill in February last to compel the return to the Western Union and Gold and Stock Telegraph companies of about $180,000 in taxes. This bill is absolutely mandatory. Another bill introduced by Mr. Irwin directs the board of claims to hear and determine the amount, and upon due proof award such sum as was paid as state taxes, under such mistake of fact or law, or paid in excess of a tax based on the capital stock employed within the state, or paid under such unconstitutional law. It was for making suitable arrangements for this back tax legislation that Clarence Cary, Esq., presented a bill to the Western Union company for $5,000, which was declared to be exorbitant by the executive officers of that corporation.

NEW YORK, April 23d, 1888.

POINTERS.

.... IT is wrong to make people learn things that they must unlearn afterwards. A man with a wrong idea is more ignorant than if he had none at all.—*J. Swinburne.*

PHILADELPHIA.

The Electric Light Trust. — The City Lighting Contracts. — The Rapid Transit Electric Railroad Company.—The Welsbach Incandescent Gas Burner.

THE trustees of the Electrical Trust, which controls all of the electrical lighting companies in this city, held a meeting a few days ago and declared a dividend of 75 cents per share. The par value of each share is $100, and the selling price about $40 per share. This is the second dividend that has been declared by the Trust within a little over six months. The first dividend was declared on October 10, and was at the rate of $1 per share.

At the meeting of the Trust the first suggestion of one of the largest Trust deals—outside of the Standard Oil—yet attempted in this country was made. This was nothing less than a proposition to consolidate all the electric lighting companies in the United States in a Trust, so as to control all the electric lighting in the country. Propositions have been made to purchase all the certificates of the Trust in Philadelphia, and there is ample capital behind the scheme to carry it out if a satisfactory deal can be made.

It is said that the electric lighting franchises of several of the large cities of the United States have already been absorbed by this new Trust syndicate, and the chances of the absorption of the Philadelphia Trust are excellent.

The scheme does not contemplate the purchase of the franchises or companies in the small towns, but only of those in such great centres as New York, Boston, Philadelphia and Chicago. There is reason to believe that the syndicate controls the electric lighting companies in New York and Boston, in which two cities the scheme originated.

The proposition made to the Trust in this city are based upon its net earnings for the past six months. None of the members of the Trust were willing to discuss the details of the proposed deal the other day.

Director Wagner has decided to continue the contracts with the electric light companies at the present prices. When, in December last, he made a three-months' contract with the companies, he referred the bids made by them for the entire year to councils for acceptance or rejection. That body has not seen fit to take action in the matter, and the director has been compelled to assume the responsibility, as the present contracts ran out on April 1. Director Wagner says the prices are about eight per cent. lower than last year's, and most of the companies have already agreed to go on with the work, and it is believed they will. The new contracts will be prepared in time to prevent any interruption of the electric lighting of the city.

The Rapid Transit Electric Railroad Company, a newly incorporated organization of this city, recently placed upon the desks of all the city councilmen, at their special meeting, prospectuses containing a request that it be allowed the use for three months of the abandoned and disused tracks on Poplar street for the purpose of demonstrating the practicability of its plans. The motive power is electricity transmitted from a copper bar in a conduit under the track to a motor in the car. The sum of $1,000,000, payable in twenty annual installments of $50,000, is offered for the privilege of running cars over the following route: A double track from 29th street and Lehigh avenue to Ridge avenue, to 28th street, to Poplar street, thence by single track to Parrish street, to Corinthian avenue, to Brown, to 19th, to Shirley, to Francis, to Brown, to Marshall, to Wood, to Sixth, to Minor, to Fifth, to Wood, to Seventh, to Spring Garden, to 11th, to Poplar, to 28th street, and to starting point. The officers are: president, Hiram Miller; vice-president, W. A. Levering; secretary, Theodore K. Vogel; treasurer, Samuel A. Newman; directors, S. P. M. Tasker, J. B. Mencke, W. A. Levering, C. N. Apple, Lewis Eckel, Franklin Noble and Hiram Noble. These gentlemen are also the incorporators, with the addition of N. E. Janney and Crawford Spear. The request of the company was not brought formally before councils.

A private exhibition was given a few days ago of the Welsbach incandescent gas burner, a contrivance invented by Dr. Carl Auer Von Welsbach, an Austrian scientist. The burner, supplied by the flame of an ordinary gas light, gives forth an intensely brilliant illumination, equal to electricity.

The ingenious Welsbach gaslight consumes the ordinary illuminating gas in such a manner as to produce absolutely perfect combustion. It is known as the Bunsen principle of combustion, attained by heating a meshwork of metals to a brilliant incandescence, from which the illumination is radiated. It produces this result by burning about one-half the quantity of gas now required for an ordinary gas burner. If it is introduced in this city it will result in reducing the cost of gas about one-half what it is at present to consumers. The Welsbach burners are very simple, and are supplied at trifling expense. It is only necessary to unscrew the ordinary burners now used on gas fixtures and substitute a Welsbach for it. Then it becomes necessary only to turn on about half the quantity of gas to get about twice the illumination. The popularity of an article of this character is apparent without comment. A stock company has been formed to bring the Welsbach into commercial recognition, and it will soon be a commodity universally known by virtue of its own merits. In the list of stockholders and managers of the corporation are several well-known Philadelphians. The stock is $100 par, of which $30 has been paid. The officers and directors consist of:

President, A. O. Granger; secretary and treasurer, S. D. Bodine; board of directors, George Philler, William Wood, Thomas Dolan, William M. Singerly, John G. Reading, A. O. Granger, William G. Warden, W. W. Gibbs, Randal Morgan, Robert Glendenning, T. J. Montgomery, A. G. Richey; advisory committee of stockholders, Henry C. Gibson, Lemuel Coffin, William T. Carter, Joseph E. Gillingham, C. P. Helfenstein, J. B. Altemus, James A. Wright, H. H. Houston, T. Wistar Brown, William Brockie, Clayton French, Thomas Cochran, A. C. Humphreys, Morton McMichael, I. V. Williamson, Wayne McVeagh.

PHILADELPHIA, April 20, 1888.

BOSTON.

A Large Amount of Underground Work Already Accomplished.—A General Franchise Granted by the Board of Aldermen.—The Company which has Obtained the Franchise.—Conduits Considered by the Assembly Committee on Mercantile Affairs.—Electric Lighting and Insurance Discussed at the Boston Electric Club.—The New England Electric Exchange; its First Quarterly Meeting.—Professor Dolbear on the Telephone Decision.—Monthly Output of Telephones.—The First Fatal Accident at the Thomson-Houston Works.—Electric Lighting at Lynn.—Magnitude of Electric Communication between Boston and New York.

HERETOFORE speculators and inventors have kept their hands off from the streets of Boston, so far as relates to underground electric systems; at least no activity has been shown in that direction. Meanwhile, the Edison Electric Light Company have put down many hundred feet of their three-wire conductors. The Western Union Telegraph Company were the early birds, and have buried a considerable quantity of wire in wrought iron pipe. The New England Telephone and Telegraph Company have down several miles of underground wires, embraced in two styles of conduit; the first consists of iron pipes embedded in asphalt; the second is the creosoted plank conduit, with longitudinal compartments and man-holes every two hundred feet.

On the evening of the 9th inst., after transacting minor business, the board of aldermen went into a committee of the whole to consider the matter of a conduit system for wires.

After the rising of the committee and the resumption of the general session, two reports were presented; the minority of the committee holding that the city was without right to construct and maintain electric conduits or to grant franchises to others for such purposes. The majority report submitted an order, which, after some discussion, was adopted, granting

To H. E. Cobb and others an exclusive franchise to construct, establish and maintain through and under the streets of the city conduits for telegraph, telephone, electric light and power communicating wires It also provides that the board of aldermen shall determine the location in the streets through which the conduits are to pass. The petitioners agree to furnish the city free of all rent and charge accommodations for all wires now owned or controlled by the city or that may hereafter be owned or controlled by said city, and to furnish and keep in repair such wires without expense to the city, and shall pay to the city all the excess of their profits of ten per cent. of the capital actually invested, and shall allow their books and accounts to be inspected at any time by the city auditor or any person whom the board of aldermen may designate.

Work shall be begun in four months from the passage of the order. The parties shall also grant to all corporations whose wires may be required to go underground reasonable accommodations, for which a uniform price, without favor, partiality or discrimination, shall be charged. All disputes shall be referred to the board of aldermen. The parties further agree that, should the city construct a sub-way in streets where conduits shall have been laid, to take up their conduits and place them in such a sub-way at their own expense. After ten years the city may purchase the franchise. Nothing granted shall affect the Edison Illuminating Company, or prevent it from laying its own conduits, or the rights granted heretofore to any individual or company to maintain underground conduits, or the vested rights, if any, of any individual or corporation in any of the streets included in the order.

The history of this corporation, which has acquired these valuable rights from the board of aldermen, is as follows:

On December 27, 1881, the board passed an order giving to W. R. Clarke, C. W. Lewis, J. F. Shorey, Fred. Allen, A. A. Nickerson, S. O. Richardson, C. Wakefield, rights and privileges in the streets of Boston to construct and maintain wires underground. On March 24, 1887, an order was presented to the board requesting permission to transfer the above privileges to the American Conduit Co.; and on the 18th of April, 1887, an order was passed by the board authorizing the transfer. On or about the 1st of May, 1887, the mayor vetoed the measure, but the aldermen were equal to the emergency, and passed the order over the veto. The American Conduit Co. "has grown" since its first inception, and today includes several so-called systems, which have been knocking about town for a considerable time, and has a good many "friends." Meanwhile the American Conduit Co. are before the legislature to perfect their title. On the 12th inst. the assembly committee on mercantile affairs gave a hearing on the orders as to placing all electric wires underground. Messrs. H. E. Cobb, R. M. Pulsifer and F. R. Chapman were represented by Mr. S. C. Powers; the Bell telephone company by Messrs. G. A. Bruce, H. N. Shepard and F. H. Williams; the Western Union Telegraph

Company by Mr. George S. Hale; and the Spaulding Conduit Company by Hon. Henry Winn. Colonel Pulsifer advocated the proposed legislation, the arguments being substantially the same as were used before the board of aldermen and which have already been fully published. He was cross-examined at much length by the opposing counsel. The advocates for the legislation proposed submitted the following bill:

Section 1. Every company incorporated for the purpose of constructing and maintaining underground conduits or pipes, through which to conduct wires for telegraphic, telephonic and electric light and power communication, shall possess the powers and privileges, and be subject to the duties, restrictions and liabilities prescribed in this chapter.

Sec. 2. Every company may, under the provisions of the following section, construct underground conduits, under and through streets, highways and public roads, and under any waters within the Commonwealth, but shall not incommode the public use of highways or public roads, nor endanger nor interrupt the navigation of any waters.

Sec. 3. The mayor and aldermen of any city or the selectmen of any town may grant to any corporation organized under this chapter a permit to construct conduits under any streets, highways or public roads, upon such terms and conditions as they may deem necessary for the proper protection of the public, and may determine the location in such street, highway, or public road through which said conduits may run; and the mayor and aldermen and selectmen of the place through which such conduits are to be located may grant an exclusive franchise for the construction and maintenance of such conduits for a term of years, if, in their opinion, public convenience and necessity require such a franchise to be granted.

Sec. 4. The mayor and aldermen or selectmen of a place in which such conduits have been constructed may order any company maintaining overhead wires for the transmission of intelligence by electricity or furnishing electric light and power, to place its wires in such conduits, if in their opinion public opinion requires such action, and said wires can be located and operated in said conduits without material injury to the business of said companies.

Sec. 5. A company shall not commence the construction of its conduits until three-fourths of its capital stock has been unconditionally subscribed for; and the directors shall, within ten days of commencing said conduits, file in the office of the secretary of the Commonwealth a sworn statement of the subscription.

Sec. 6. A company shall not at any time contract or owe debts to a larger amount than one-half part of its capital stock actually paid in.

Sec. 7. The president and treasurer of each company shall be jointly and severally liable for all its indebtedness, in case of wilful neglect or omission on their part to comply with any of the provisions of this chapter.

Sec. 8. Every company shall construct its conduits in such a manner as shall be satisfactory to the mayor and aldermen or selectmen granting the franchise.

Sec. 9. Every company shall provide suitable accommodations for such telegraph, telephone, and electric light and power companies as may desire to place the wires owned or controlled by them in said conduits; and also for such wires as the mayor and aldermen or board of selectmen may order to be placed in said conduits.

Sec. 10. Every company constructing and maintaining such conduits may charge rent to, and collect of, telegraph, telephone and electric light and power companies, for the use of said conduits, and the mayor and aldermen or selectmen of the place where the conduits are located may fix and regulate the rates or tolls which said company shall charge its customers.

Sec 11. The mayor and aldermen of any city and the selectmen of any town may establish reasonable regulations relating to the construction and maintenance of conduits by companies overissued under this chapter.

Mr. Powers offered in print the evidence of hearings before the aldermen, the annual report of the board of electrical control of New York, etc., as establishing the feasibility and desirability of placing these wires underground, and rested the presentation of his case at this point. The committee then adjourned until the 19th, when the remonstrants will begin to submit their side of the case.

On the 27th ult., in response to an invitation extended to representatives of various electric companies to assemble and talk over equitable means for harmonizing the subject of insurance inspection and the effective installation of electric light plants desired by the different electric light companies, about fifty electricians assembled at the rooms of the Boston Electric Club. Mr. P. H. Alexander was chosen chairman. No formal votes or resolutions were passed, but an interesting discussion was carried on. It was recognized on both sides that there is a mutuality of interest, and that the highest degree of safety against fire is of money value to the electric companies in the way of reputation as well as to the insurance companies in the diminution of risk. The chief debatable points appeared to be as to the necessity of having "converters" placed outside of buildings, as the insurance companies require; as to the proper character in respect to material and size of fusible plugs, and as to the nearness to each other in which parallel lines of electric light wires may be extended. After the debate there seemed to be a pretty general recognition on both sides that until further advance is made in the art the converters had better be kept outside.

Mr. Thomas D. Lockwood spoke in behalf of the telephone wires, and thought that the several electric companies should work together in the stringing of wires, so that each should be protected from the other.

Mr. S. E. Barton, representing the New England Insurance Exchange, said that that organization will probably soon adopt a lower schedule of insurance risks for buildings of a certain class lighted by the incandescent system, that system of lighting when properly put in and subject to their inspection being recognized as making a safer risk than either gas lighting or kerosene.

An invitation having been brought to the meeting by Professor Cross to visit the electric laboratory of the Institute of Technology, and to witness the operation of the alternating system of electric lighting recently installed there, an adjournment was taken for this purpose.

At the evening session the discussion of various topics was continued, and it was voted to form an organization, to be known as the New England Electric Exchange. Officers were chosen as follows: president, P. H. Alexander, of the Sawyer-Man company; secretary, H. B. Cram, of the Bernstein company; referees, Dr. Robert Amory, Frank Ridlon and G. W. Davenport. The trustees will be the medium of communication between the members and the New England Insurance Exchange. The board is to report at a meeting to be held in April a plan under which license may be granted to employés of electric light stations, and to those employed in the wiring and installation of electric light plants.

The New England Electric Exchange held its first quarterly meeting on the 9th inst., at the rooms of the electric club on Boylston street, president Alexander in the chair. The board of referees elected at the recent meeting of gentlemen connected with electric lighting interests, at which meeting the exchange was formed, submitted a report that embodied the proceedings of that meeting, and gave an account of the several conferences held by them with gentlemen representing the fire insurance interests, in reference to the matter of licenses being granted by the exchange to persons practically engaged in the installation or operation of electric plants, with the object of inducing the insurance underwriters to recommend the introduction of electricity in preference to other means for producing artificial illumination and for power. A constitution was also submitted and adopted. The following-named officers were then elected: president, P. H. Alexander; secretary-treasurer, H. B. Cram; directors, the president and secretary-treasurer, and Messrs. Robert Amory, Frank Ridlon and George W. Davenport.

Professor Dolbear is reported as saying, apropos of the recent telephone decision, that it as a whole surprised him, not only in the parts affecting himself, but the other contestants as well. "As for the Drawbaugh people," said he, "they got more than I expected they would. I had no idea that their claim for priority of invention would be sustained by a single judge, but it seems that three out of the seven were satisfied that to Drawbaugh belongs the credit of the invention. They may well be satisfied with the decision; and I am of opinion that they were more successful than they expected to be, and, encouraged by their success, they may endeavor to have the case reopened. No such patent was ever issued before, and the patent office refuses to issue such a broad one again; but the Supreme Court will not cancel the one already issued. I have an altogether different method from Bell's, and a better one, as it is free from many defects always present in his."

The statement of the output of telephones by the American Bell company for the month ended March 20 is tabulated herewith:

March—	1888.	1887.	Increase.
Gross output	4,106	4,372	*266
Instruments returned	1,621	1.452	169
Net output	2,485	2,920	*435
Dec. 21 to March 20—			
Gross output	12,108	11,759	356
Instruments returned	5,381	5,326	55
Net output	6,727	6,425	302

*Decrease.

The Thomson-Houston Electric Company, of Lynn, record the first fatal accident at their works in West Lynn. At eleven o'clock Friday forenoon, March 31, Harry H. Levitt, twenty-two years of age, received a shock from a circuit on which there were 52 arc lamps. The electric current which passed through his body being equal to about 40 h. p., his death was instantaneous. An artificial respiration was kept up for an hour by Professor Thomson, Superintendent Rice and others, but without avail. Levitt was taking readings from two instruments which should have been placed so far apart that he could touch but one at a time. Instead of this, by his own carelessness, it is said, the instruments were placed close together. His hands were both badly burned. His home was in Philadelphia. His father is a traveling agent for the Thomson-Houston company.

The committee on manufactures reported a bill to consolidate the Lynn Gas Light Company and the Lynn Electric Lighting Company, to be the Lynn Gas and Electric Company, if they get the written consent of the gas commissioners. It is to have the rights and privileges of both the present companies, and to have a capital equal to the united capital of the two companies. The property of the new corporation is to be liable for the debts of each of the old companies.

There are usually 100 direct telegraph wires and 16 telephone wires between Boston and New York. Sixty-two of the telegraph wires belong to the Western Union company. The Mutual Union has 17, the Commercial Cable Company has 10 wires, and there are many private wires.

BOSTON, April 16, 1888.

Electric Street Railways.

THE third of the series of papers before the Chicago Electric Club on the subject of the Continuous Current vs. the Alternating, was read by Mr. E. P. Warner on April 2d. For the sake of discussion Mr. Warner advocated the merits of the continuous current system. At the meeting of April 16th the series of papers in the discussion was interrupted for a paper by Mr. C. H. Rudd, of the Western Electric Company, on a device for testing electric light circuits while in operation.

Professor Badt will read his paper on the Alternating System at a special meeting on April 23d, and the interest in the discussion is so lively, and the subject is one which is developing so many new features at the present time, that instead of terminating the discussion with Professor Badt's paper it has been decided to extend it by three more papers, one advocating the continuous current, another the alternating, and the last to summarize the results of the entire discussion.

The Chicago Electric Club has considerably enlarged and improved its quarters by taking in the entire floor of the building in which its rooms are located. Some of the members urged objections to the present location, but after considerable search it was decided to renew the lease of the club's present quarters with the additional rooms which were offered, for a period of two years, in the lapse of which time it is the purpose of the club to secure a commodious club house.

The following resolution was introduced by C. A. Brown at the last meeting of the Chicago Electric Club, and met unanimous approval:
